The primary purpose of this address, however, is the protection of the public against the ill consequences, which grow out of the wide divergence among our schools of medicine, with respect to standards of educational requirements and facilities for teaching. The time is at hand when efforts should be made to effect uniformity in the teaching of the scientific branches of medicine, more especially anatomy, physiology, chemistry, pathology and diagnosis, both in irregular and regular schools of medicine, since a knowledge of these subjects is indispensably necessary as a background for any rational system of treatment. If this were accomplished a certain, definite standard, considerably higher than that which obtains at present in some socalled schools of physiotherapy, would be reached. Again, the subjects before mentioned cannot be learned, as is true of many others, in the school of experience, after graduation. Simply to let the light of publicity play over the present educational system as it affects a most vital portion of the training necessary to make competent healers of human ills cannot be justly criticized. Surely, if credible testimony to show that in certain irregular schools preparation for the successful handling of the diseases to which man is liable is inadequate in important particulars, a strong moral sentiment in favor of bringing about the reform proposed should be easily possible.

A review of the present situation, given below, will convince the most skeptical that the requirements of the regular schools of medicine, in which we include homeopathy and eclecticism, demand that the student shall be properly trained in the scientific subjects mentioned above, while those of the drugless cults, e. g., osteopathy and chiropractic, demand far too little instruction in these subjects by comparison.

It might be found to be feasible to combine the institutional interests for the training of all medical students in the scientific branches enumerated above; this would tend to eliminate duplication of effort; but more than this it would insure to the public service founded upon knowledge that is essential to the pursuit of any form of practical study and treatment of disease. It seems to me the state should accept this dictum, and nothing less, in the interests of the general public.

I feel strongly that if a course, the equivalent of the first two years in a regular medical school, in these basal sciences, including diagnosis, were required of the students of all medical sects, the folly of attempting to treat every form of illness by physiotherapy, which has but a limited field of usefulness, would be universally appreciated by students. Obviously, unity of training in these subjects would deter many from taking up the various cults and isms now in vogue. The student would learn to recognize the importance of coordination and cooperation of the clinical and pathological phases of medicine; in short, their interdependence.

The triumphs of the laboratory, without which the modern clinical worker could not attain his aims, are to a great extent ignored by the osteopaths and the practitioners of other irregular cults. The laity should be informed of this fact and also that a diagnosis rarely rests secure upon either the clinical or pathological findings alone, but upon a complete composite picture of these jointly. At all events, the laboratory is often an aid in the search for the seat of diseases, which, be it recollected, may be located anywhere in the body, or may involve the entire organism, the teaching of certain sects at variance with this view notwithstanding.

We can excuse the superstitious efforts of the native Turk who aims to keep off disease by tying beads of bright color on the hair of his children, but it is not so easy to conceive of intelligent men and women seeking the professional services of members of a cult who display lack of knowledge of those basic sciences on which rational medicine must rest, when afflicted with more or less obscure and often serious disease. And yet this is taking place to an extent daily that is appalling to educated physicians. Indeed, it has been estimated that not less than one third of the population of this country is relying upon drugless cults and isms for relief from human ills at the present day.

Time was, within the quarter century last passed, when the medical colleges of this country were not of a quality to justify a feeling of exultation. Since then, however, undergraduate medical education has been standardized to a point at which it can be said to meet the needs of the general public with proper organization and the application of good business methods. This has been accomplished in connection with the regular schools of medicine largely through the labors of the Council on Medical Education of the American Medical Association.

The fact that a large portion of the general public, however, is patronizing irregular, drugless cults whose schools occupy a distinctly low position, the system of medical education as a whole in this country at the present writing is but little more satisfactory than it was a couple of decades ago. As stated elsewhere, "Without doubt, the regular schools of medicine have a just and decided claim to public recognition, and it is the clear duty of this association to impress the public mind with the fact that the difference in educational standards between regular and irregular schools of medicine is an injustice to the body politic, which the people themselves must recognize and then correct" (1).

In this era of social reconstruction the medical profession is called upon to bear no small part in the work of plotting the new chart. What history will record it did in this relationship depends upon leadership and character of citizenship. That distinguished statesman and farseeing member of the medical profession, Sir Auckland Geddes (2), in speaking of its civic side, laments the fact, shown by bitter experience, that doctors do not, as they should, all see "a little further and a little more clearly than the lay world in the direction in which the emotion of human betterment is driving us, those now middle-aged might live to rejoice at the recognition of medical science as the main basis of political action, for all political action aims, nominally, at least, to secure the health and wellbeing of the people." The preparation for this task involves not only mature citizenship on the part of physicians, but also the cultivation of the true scientific spirit.

It is to be deplored, therefore, that there are so many irregular practitioners whose training and professional work are not in relation either with the fundamental, scientific branches of medicine or that scientific spirit so necessary in the clinical study of disease. Investing, as they do, their practice with awe and daily committing flagrant impositions on the fear of human sufferers, the practitioners of the various newer cults are now menacing the very existence, progress and development of sane, rational, scientific medicine.

It seems to me that a real peril to legitimate medicine lies in the mass of people who patronize the pretenders engaged in these fundamentally defective practices, which should be displaced. Those who practise these cults enjoy special advantages and privileges by holding sufficient political power—an instance of class legislation, which should not be permitted in any well regulated social organization. Again, to have permitted these irregular schools to establish themselves at a time when our regular medical schools, almost without exception, recognized the importance of, and effected a vital union with, universities, is cause for the keenest regret.

It seems to me that in every possible way there should be public insistence on what it means to submit disease processes to men and women inadequately trained in physical diagnosis, laboratory methods and the scientific branches of medicine. There are mournful examples on every hand of those who overvalue the advantages of physiotherapy by such healers and as the result they find themselves in a worse plight than before, not to speak of serious disasters which are not rare.

Without doubt, if the accomplishment of the training in laboratory methods and fundamental sciences could be unified for all schools, regular and irregular, it would mean much for the progress of American civilization. We might then look forward with bright confidence to the early disappearance of certain sects which have come into vogue, each with a little virtue behind it, but which can never, as has been claimed, open the approach to the treatment of all forms of illness. The plan herein advocated embraces the thought that students from all schools would be required to qualify, by passing a single state board of examiners, for the study of the practical aspects of medicine, including treatment.

Obviously such a modification of the medical educational processes as proposed above can come only in response to a popular demand; only if the people get behind it. Meanwhile, time must be given for the development and crystallization of public opinion under the tactful and systematic efforts of those who see the necessity for the change advocated and share an active desire to bring it about.

It is always difficult to break down the barriers of custom, and it would be manifestly foolish to doom the result of our efforts to failure by merely giving expression to a few idealistic phrases. The present status of marked inequality in the requirements of different schools of practice, more particularly so far as the scientific branches are concerned, must be analyzed and repeatedly presented in detail to the public mind. This is the plan to be pursued no matter how slow and tortuous our steps in progress toward the goal that it is so desirable to achieve.

One of the most important things in this connection is the enlistment of all American medical organizations in a combined effort to establish uniformity of standards with regard to instruction in the scientific branches of medicine. In view of the importance of this question, it is here proposed that the American Therapeutic Society appoint a special committee with the object of seeking the coöperation of similar committees of other medical associations in the proper solution of this important problem. A moment's reflection will convince the members of these bodies that this is one of the ills of the healing art crying loudest to be cured, so that their active cooperation from the viewpoint of the highest motive should be easily obtainable.

The claim cannot be made that the change proposed in medical education is at variance with accepted dicta, hence smacks of radicalism, and is to be attacked as being intellectually dishonest or self-exploiting. Again, it is not an instance in which an effort is being made to stigmatize the inferiority of those who may in their ignorance honestly differ from the viewpoints of the regular profession; but of a desire to render a real public service—an ideal to which the organized medical profession as a whole has ever been committed.

As stated in the recent address by Dr. John B. Deaver, "We ask only that the individuals practising these cults and 'pathies' become so sensible of their responsibilities as to acquire an education similar in breadth and training to that which, after long ages, the medical profession deems prerequisite to the treatment of disease" (3). To a great extent at least it must be confessed, the regular profession is to be held responsible for the faults of the present status of the healing art. For example, massage, which had been neglected by physicians as a rule for more than a score of years, became superseded by osteopathy, which is now one of the leading and most popular drugless cults.

Unfortunately, the form of physiotherapy, masquerading under the name of osteopathy, pretends to be a "system of medicine supplanting all internal medication and as such is teaching its patrons false doctrines and systematically estranging them from the broad principles of medicine" (4). This regrettable situation, from the viewpoint of the public interests, gave birth later to other mongrels, e. g., chiropractors and neuropaths. Osteopathy is founded upon the idea that "all diseases are caused by either an interference of the blood or nerve supply, or both." To quote further: "An excess or lack of acids, a nervous irritation (nervous dyspepsia), a lack of tonicity (prolapsed stomach), ulceration and many other conditions may be traced to this little deflection of the vertebra from its natural position. What more rational treatment could there be than to have the position of the vertebræ corrected, the nerve forces released, the blood supply made normal and the chemical laboratory permitted to do its perfect work"? (5)

It is worthy of note, as an example of imposition on the fears of patients, that while the osteopath detects a dislocated vertebra in all subjects presenting themselves for treatment, the chiropractor almost regularly finds that two are displaced and need to be readjusted. It would seem therefore that the assignment of massage to a rank far below its merits by the regular profession gave opportunity for exploiting it in a modified form as a "cureall," under new and unfortunate names.

An added reason why irregular cults flourish is contained in a statement issued by the Medical Society of the County of New York, to wit: "Chiropractic publicity has been built upon the ruins of the public's shattered faith in patent medicines. The chiropractor realizes that the public seeks a simple explanation of the cause of disease and appreciates the public's impatience with intricate scientific explanations that are beyond the ordinary man's understanding." Public opinion with respect to the school of osteopathy, and the same is even more strikingly true of that of chiropractic, has been deliberately and consistently deceived and corrupted through propaganda, not only in the press but also through discussion.

There is another defect in the regular medical service of the country to which the organized profession has not been fully awake. Not only has there been a falling off in the numerical strength of the general practitioner, more particularly in the rural districts of this country, but he has found himself handicapped by a lack of instruments of precision and out of touch with modern laboratory methods, and as a consequence has been rendering a superficial and often an inferior medical service.

This unfortunate process of retrogression naturally has affected more especially those practitioners who received their training two decades ago and upward, while those who have entered the profession more recently, realizing the fate of their senior confrères, have been loath to enter this field of practice. The regular profession is confronted by the problem of establishing a more efficient medical service, more particularly for that large element of the population which lies between the rich and the poor—the great mass ministered to by the general practitioner. The two classes of society, the rich and the poor, are receiving ample care under existing conditions.

Doubtless those who practice irregular cults derive their chief support from this large middle class of society; they are persons who are selfsupporting and willing to pay, but cannot afford the charges made by a group of skilled specialists. It has been affirmed that this defect is met by the advent of the small community hospital with its well equipped laboratory.

In my view, a more effective remedy is the diagnostic or group pay clinic, rightly organized and conducted. The question of the abuse of these institutions by private aggregations of physicians does not concern the present discussion. In order to avoid misuse, however, diagnostic or group clinics should be created so far as possible only in connection with established hospitals and dispensary services. Again, their function includes the treatment of disease—a phase of activity which is too often overlooked.

Uniformity of teaching in the fundamental subjects should be one of the guiding principles of all medical education. The medical practitioner is poor at diagnosis and treatment if he is deficient in physiology and physiological chemistry and cannot interpret correctly scientific results from the clinical or pathological laboratory. And no matter how skillful in manipulation the osteopath may be, he is a pure empiric, feeble in clinical medicine, physiology and pathology—three branches which must be mastered to an appreciable extent and coordinated in the prosecution of the work of any practitioner. It is justifiable to assume that if the public were fully informed on the problem of choosing a proper medical adviser, acute diseases in particular would not be committed to the care of the osteopath or chiropractor, as is the case today, and thus often allowed to develop until they pass beyond human aid.

Let us next compare the standards of the regular and irregular schools so far as they relate to the basic scientific subjects. In the curricula of the first class medical schools, two years are devoted to these branches almost exclusively, after meeting the entrance requirements which are the first two years of a college course or, as is true of some universities, an A. B. degree.

On the other hand, a comprehensive series of facts showing the status of the requirements of irregular, yet legally recognized schools, reveals a strange contract. For example, entrance requirement of leading osteopathic schools is the equivalent of a standard four year high school course. When, as is the case in Pennsylvania, it is necessary to have credits for one year's work in physics, chemistry and biology in order to obtain a qualifying certificate, these subjects are taught during the first year of the osteopathic course, whereas the students of the regular schools have had collegiate chemistry and physics when they enter.

A glance at the following table will show by comparison the differences in hours between irregular and regular schools of medicine, so far as the scientific branches are concerned:

Subjects	*Irregular (Osteopathic, etc.)*	*Regular*
Anatomy	570 hours	752 hours
Physiology	118 hours	400 hours
Physiological chemistry	144 hours	284 hours
Pathology	260 hours	412 hours
Bacteriology	144 hours	206 hours
Totals	1236 hours	2054 hours

From what has been presented it seems to me that every fair minded person will admit that the state should provide laws and regulations that would unify the teaching of these important, fundamental branches of medicine. It should be made evident to the public that the same discrepancy obtains in favor of the Class A regular schools, upon comparison of the curricula with regard to opportunities and methods, which are fundamentally vital to the clinical branches or those that enable the student to arrive at a correct diagnosis and a basis for appropriate treatment.

The more urgent needs of these small yet constantly growing cults, however, are competent teachers and well equipped laboratories of chemistry, physiology and pathology, where students can be helped to trace the clinical manifestations, early and late, of diseases, back to their underlying causes. Says William H. Welch (6) in speaking of the marvelous activity and expansion of the laboratory in recent times: "This remarkable growth of laboratories for the cultivation of the various medical sciences has been at once the cause and the result of the rapid progress of medicine in recent years."

The question naturally obtrudes itself here, Shall the regular medical profession longer tolerate this situation without so much as a protest? What greater service could the medical profession render the public than to convince popular opinion that a certain standard of scientific attainment must be insisted upon for all, before the student can proceed to the practical subjects, including the cure and treatment of disease in the school of his choice. While this would be a large contract, it would be found to be practicable if it were possible to enlist the concerted action of all medical organizations, a solidified force with a definite propaganda, and if the American Medical Association were to assume the leadership in the movement.

The American Medical Association is entitled to speak with authority because of its great contribution to the cause of medical education and the spirit and influence of its activities in elevating the standard of qualifications of the regular medical service of this country. It seems to me that this organization, reinforced by other national and local societies, should be prompt in bringing its power to bear against the evils growing out of the minimal requirements in the scientific branches under discussion among our irregular medical schools, and should aim to effect a widely enlightened public and the needed modifications of existing laws and regulations. The American Therapeutic Society could be depended upon to assume a large share of the propaganda activities required and to this association will, I trust, belong the credit of launching the movement. Surely, if our legislators of integrity had their minds directed toward the present state of medical education as carried on by these newer cults, they could be depended upon to take a determined stand against it.

Unfairness to the regular schools as to entrance and graduation requirements ultimately will cause injury of a serious nature to the public health interests. Without doubt, if this fact were duly appreciated, revision of our state laws governing medical licensure would receive the endorsement of the enlightened element of the laity. Indeed, it would not be reasonable to suppose that intelligent, right thinking citizens, whether professional or lay, could rest in selfsatisfied contemplation of the situation.

The deficient teaching of physiotherapy in our medical schools is a side problem which may be conveniently referred to here. Failure of teachers to fulfill their duty in this respect has invited and inspired cults whose devotees are using a little technical knowledge ostensibly in the interests of the state, but in reality to reap pecuniary reward out of them. How to escape from this rapacious medical situation of today lies, in part at least, it seems to me, in a pedagogic reorganization of the teaching of therapeutics. The student's mind has been too much conducted into wrong paths in the past, e. g., into that of drug therapy, leaving him blind to equally important means to be found in the field of physiotherapy, including that most valuable measure, massage.

In this connection it is pleasing to record a departure from the old classical, traditional arrangement of subjects in textbooks in the valuable work entitled *The Principles of Therapeutics* by Thomas G. Osborne. Not only has he presented the subject in a way that must prove highly useful to the practising physician, but the physical measures have also been stressed to a degree commensurate with their actual importance as remedial aids. It is to be hoped that our undergraduate courses in applied therapeutics will be similarly modified to meet the urgent necessities of the medical profession in the future.

As a society we should make every effort to safeguard the interests of the profession by impressing upon the minds of those teaching pharmacology and therapeutics in our medical schools, the necessity for an all round training in those subjects so as to insure its complete availability for the general practitioner. The American Therapeutic Society if alive to ever threatening dangers, can in this manner also become ultimately the protector of the public. It is necessary, however, that we realize our responsibilities and appreciate our power when exerted individually and collectively to the fullest extent, in a matter in which the public is so vitally concerned. Surely, the present situation affords an exceptionally good opportunity to institute a movement in the direction of improved methods of teaching the treatment of disease.

The report of the committee, appointed one year ago on a plan for teaching therapeutics, will be, I trust, adopted by this society at the present session and a copy sent to the proper authorities of every medical school in the country. The curriculum presented by this committee of the whole membership and of which Dr. Oliver T. Osborne is the chairman, sets forth a curriculum for the teaching of the large and important subject of the treatment and management of disease, which embraces all useful measures. The American Therapeutic Society should realize that in supporting the report of the committee, it will be sustaining broad ideals and insuring the dawn of a new day in the teaching of therapeutics.

Another function of this society, that of elevating and improving the science and art of pharmacy, as well as maintaining a standard of professional ethics and honesty among pharmacists, is one meriting our serious consideration. Thanks to the persistent and well directed efforts of Dr. Francis E. Stewart, our knowledge of the meaning and results of the cooperation between the medical and pharmaceutical professions have been greatly facilitated. As a society, we should make greater efforts to educate these two professions in rational drug therapy based upon the United States Pharmacopœia. Let us use our fullest influence to the end that the line between the commercial drug business and the pharmaceutical profession may be a distinct and broad one; and establish the pharmacopœia as a guide in the use of drugs as remedial agents.

The medical profession has been justly assailed as neglectful of certain aspects of the science and art of therapeutics. For example, M. Nicoll, Jr. (7), pertinently remarks, "There is growing up a passion for diagnosis to the exclusion of medical care and treatment, save in those conditions for which specific remedies have been discovered." This is an added reason why patients, who seek relief from their sufferings, are applying in increasing numbers to pretenders, mountebanks and charlatans.

Says Wynn (8), in speaking of the application of the common natural agencies in relation to the cure of disease: "Physicians have failed, first, because medical schools have not taught these things thoroughly or systematically; second, because hospitals have not provided the facilities or a staff of teachers thoroughly competent to instruct; and, third, because nurses have not received efficient instruction in carrying out the methods. Neglect to give these subjects the attention they merit in therapy has been more responsible than aught else for the development of recent sects in medicine."

From the preceding discussion a comprehensive program for the protection of the public against incompetent and partially trained practitioners must have three principal purposes: 1, the creation of a common standard of entrance requirements for all schools and systems of medicine; 2, to bring about uniform training for all in the subjects of anatomy, physiology, physiological chemistry, pathology and diagnosis, followed by an examination by a single state board of medical examiners in these branches; and, 3, better and more comprehensive teaching of physical therapy, in our regular schools of medicine.

The attainment of the first two purposes necessitates, as emphasized in the foregoing discussion, the development of an intelligently educated public opinion. To this end, as before pointed out, we must harness all available forces in the medical world and those of allied agencies that make for communal betterment and national improvement. The third purpose, not purely from selfinterest, but from a far higher motive, demands the placing of teaching of the treatment of disease on a sane and solid foundation.

1605 Walnut Street.

A Medical School Curriculum Leading to Rational Therapy Recommended by The American Therapeutic Society

By OLIVER T. OSBORNE, M.D.,
New Haven, Conn.,
Professor of Therapeutics, Yale University.

GENERAL PLAN.

It is understood that the following plan is arranged for the regular four year course leading to the medical degree. Some changes would be advisable for colleges that have a five or six year course in medicine.

1. A good working knowledge of inorganic and organic chemistry is a necessary requirement for entrance into a medical school.

2. Biochemistry and physiology should be taught principally in the first medical school year, but the chemistry of the tissues and secretions, and nutritional and metabolic processes should be repeatedly presented to the medical student throughout his course in pharmacology and therapeutics, so that he will constantly bear in mind the functions and the chemical reactions of the diseased parts which he is called upon to treat.

3. Pharmacology should be taught principally in the second medical school year by assigned lessons in a textbook and by personal participation, under supervision of the instructor, in the demonstration of the action of therapeutically useful drugs. The close relationship between physiology and pharmacology should constantly be impressed upon the student.

Didactic instruction should be given and, when possible, quizzes based on textbook lessons should be held, on all useful drugs the action of which cannot be pharmacologically demonstrated, such as quinine, mercury, iodides, iron, and others. Also, such instruction should be given concerning the value of drugs used externally, as antiseptics, germicides, and those used as stimulants or sedatives to the skin and mucous membranes.

4. The principles of therapeutics should be taught in the first half of the third year, and must be preceded by the study of the pathology of disease, as unless the physiology and the pathology of a part, or of a diseased condition, are understood a rational application of therapeutic measures cannot be made.

5. Applied therapeutics should be preceded by the instruction in physical diagnosis, the clinical laboratory instruction, and the didactic and textbook instruction of internal medicine. Clinical instruction in therapy, that is, applied therapeutics, should be begun at the bedside, in the latter half of the third year and should continue throughout the fourth year. Didactic instruction in applied therapeutics should, during the third year, supplement the bedside instruction. The part that foods play in diseases of metabolism and the proper diet for each individual patient should be carefully presented to the student so that he will recognize the importance of dietotherapy.

Preferably hospital therapeutic instruction should precede dispensary therapeutic instruction, as more scientific diagnoses can be made and the results of treatment can be watched in the former cases. Also, all too frequently dispensary clinical teaching is given by clinicians who are not teachers and who do not have the time to give attention to the details of the dispensary cases. Therefore the young medical student, as yet unskilled in internal medicine and in the treatment of disease, acquires habits of carelessness, especially in therapy. Very many times he does not know of just what the treatment consists, especially the medicinal treatment, and modifications of diet are not carefully outlined to the patient, and, even if outlined, they are not likely to be carried out. Therefore, to repeat, dispensary instruction in therapeutics is many times a failure. It is a well known fact that more medical experience is required to properly diagnose and treat an office patient than a patient who is under constant supervision, as in a hospital bed.

Throughout the whole course of the student's hospital and dispensary clinical instruction the effect, success or failure of any drug or physical treatment given should be brought emphatically to his attention.

It would seem best that the student should learn early in his clinical course what rational therapy is, so that he may start his clinical career with a good basic knowledge of therapeutics, rather than to wait until the fourth year for such instruction.

6. While instruction in special therapeutic measures, namely, physiotherapy in all its branches, dietotherapy, and similar branches, should be given in the fourth year, the value of these measures should be discussed and taught the student throughout his clinical course, namely, from the beginning of the third year. While a great deal of time cannot be given to any one of these special physical therapies in the present crowded state of the curriculum in the undergraduate course, the importance of these various measures in individual instances should be repeatedly brought to the attention of the student.

If the student has not received, at some time in his previous three year course, instruction on not only the general subject of nutrition, but also on the problems of nutrition as related to disease and diseased conditions, such instruction should be given early in the fourth year. Also, if he has not received instruction on the intestinal flora and the relation of intestinal bacteriology to disease, and the relation of focal infection to digestive, nutritional and organic disturbances, he should receive such instruction during this fourth year.

It is unimportant whether the instruction in physiotherapy is given in part in the third year and the remainder in the fourth, or that it is all given in the fourth. It is important that each student receives some such instruction before he graduates. The better he understands the application and value of physiotherapeutic measures, the fewer of his future patients will seek pseudopractitioners.

SCHEDULE IN DETAIL.

Pharmacology, About One Hundred and Fifty Hours.

The basis of the study of pharmacology should be a book that has physiology, nutrition, up to date metabolism and biochemistry as well as physical chemistry as a background. Such a book on pharmacology should not only give the pharmacologic facts evolved by scientific investigation, but should also state the clinical reactions of drugs discovered by empirical methods. The student should be required to carefully study, in a textbook, the function, chemical reactions, and pharmacological activities of a drug before he assists in, or observes, the demonstration of such action by the instructor.

The action of only useful drugs should be shown to students in the regular course, and each student should take part, when possible, in the demonstration of the activity of these drugs. Laboratory demonstrations which have occurred in the course on physiology should not be repeated in the pharmacological laboratory except as needed to demonstrate the action of some drug; that is, laboratory demonstrations should not be duplicated in the two courses of physiology and pharmacology. Pharmacological investigations of new drugs or of poisons that are never used medicinally should not be given in the regular course, but may be utilized for elective research work.

It should be emphasized that it is impossible to demonstrate on animals in the laboratory the activity of many useful drugs. Consequently the action of these drugs must be learned from textbook and didactic instruction. Frequent quizzes should be held during this course. Throughout this laboratory course in pharmacology the students may be divided into groups (the best method) to serve as personal assistants to the instructors; or they may be taught in small classes by laboratory demonstrations. Two objects should be kept in mind: one is for each student to be able to closely observe the actual demonstration or experiment; the other is that a student should not be allowed to waste his time in a laboratory, standing around, doing nothing, seeing nothing, and perhaps hearing nothing. Too much time is wasted in the laboratories of medical schools.

TOXICOLOGY.

This subject should be taught by lectures and demonstrations, and the treatment of the principal poisons should be outlined. Though inorganic chemistry is a requirement for entrance into the medical schools, and such previous instruction may have included chemical toxicology, nevertheless some definite didactic instruction should be given on chemical poisonings, as well as on gas poisonings, and on poisoning by the drugs which are most commonly used with suicidal or murderous intent. The treatment of such poisonings should be thoroughly impressed upon the student, and he should be instructed, by demonstrations, in the methods used to combat such common conditions as illuminating gas poisoning and too profound ether and chloroform narcosis.

The number of hours required for such teaching depends upon whether such instruction is given in one course or in several departments; as, for instance, the instruction on the use of anesthetics and anesthesia may take up part of this instruction in toxicology.

It should be the duty of the instructor in pharmacology to especially emphasize the action of an overdose of a drug and the action of a toxic dose, and to outline the treatment to combat a poisonous dose of each drug while it is under discussion.

While it is not advisable to offer a rigid program for teaching toxicology, it should be emphasized that this subject has been neglected in medical schools, and many a medical man, in an emergency, wishes that he knew more about the symptoms and treatment of poisons. Also when he is called to the witness stand he quickly realizes his shortcomings in this line, unless he was forewarned and had time to read up the subject.

Instruction on toxicology should run coincidentally with pharmacology, and the special lectures necessary to complete the subject should immediately follow the course in pharmacology.

DRUGS AND THEIR PREPARATIONS.

While the term materia medica is more or less obsolete and the study of botany is unnecessary in a medical school, and while it is rarely that the medical man has any necessity for knowing the appearance of medicinal plants and crude drugs, there nevertheless should be a short lecture course from a laboratory table, really a demonstration, on the useful crude vegetable drugs and of the important mineral and chemical substances that are valuable in the medicinal treatment of disease. Also the instructor, who should understand pharmacy, should demonstrate the methods of making one or more of each of the various classes of pharmacopœial preparations, such as tinctures, fluidextracts, ointments, etc. Emphasis should be laid on the deterioration from light, heat and time of many of the organic drugs and their preparations, also on the changes that occur in the chemical drugs. In other words, the impression should be made upon the student that it is vital that his patient obtains a fresh preparation of a carefully selected and properly cared for crude drug. The refinements of assaying and the determinations of the alkaloidal content of drugs are not part of the medical student's or practitioner's work. He must rely on the honest pharmaceutical firm and the skilled pharmacist to give him the drugs and preparations that are up to standard, based on the requirements of the United States Pharmacopœia.

The instructor in this course should give the student a list of the various synonyms and the trademark names of similar drugs. He also should outline the most obnoxious of the nostrum frauds. The student should be shown the ingredients of many of the proprietary mixtures, and his attention should be called to the drug that is active, and its simplicity when stripped of its camouflage.

The tablet triturates that are valuable and useful should be shown the student, and he should be taught that when he uses a tablet containing a mixture of drugs he should always know the ingredients and their amounts. He should also be shown hypodermic tablets, the various ampoules for hypodermic medication, antiserum and vaccine preparations, and the packages in which they are marketed.

The instructor should also demonstrate some of the gross chemical and pharmacal incompatibilities. Physiological incompatibilities should be taught in the course on pharmacology.

Instruction should also be given in the weights and measures used in compounding prescriptions.

This whole course should consist of not more than twenty lectures, and should run coincidently with, or immediately follow, the instruction in pharmacology in the second year.

Toward the end of this second year or during the summer vacation between the second and third years, or early in the third year, one or two students at a time should be assigned to work as underassistants in the drugroom of the hospital or dispensary, in order that each student may observe, and when possible actually assist, under the instructor or pharmacist, in putting up prescriptions. This is the only way that he will learn, 1, the use of weights and measures, 2, the general appearance of drugs and their preparations, 3, the appearance of and methods of dispensing ethical ready prepared capsules, tablets and liquid preparations, 4, the method of compounding and dispensing prescriptions.

The number of hours required in this course should not be less than twenty-five, and wherever classes are small and opportunity offers, fifty hours is a better requirement.

The head of the department of pharmacology or therapeutics, in whichever department this course is given, should allow a student, when opportunity offers, to obtain this pharmacal instruction in the prescription department of some drug store, the student bringing a certificate of having spent the required number of hours as an assistant in such a store.

While some few medical schools may give a regular pharmacal course, in the present crowded curriculum it is unwise to require students to waste their time in a pharmacal laboratory. The method above outlined will give the student all the instruction he needs in pharmacy, and also gives him an understanding of what the pharmacist must do to properly compound or fill the prescription presented to him.

PRESCRIPTION WRITING.

This course should be given in the last part of the second year, and the primary instruction should comprise not less than ten hours. Instruction should be given by quizzes based on a textbook that describes weights and measures, dosage, methods of administering drugs and the method of writing prescriptions. Most textbooks on pharmacology devote a chapter to this subject.

It is urged that in view of the international use of the metric system of weights and measures and the use of this system by all scientific experimenters, the metric system be universally taught medical students.

The Committee of One Hundred on a standard curriculum for medical colleges, under the direction of the Council on Medical Education, some years ago reported through its subcommittee on pharmacology, toxicology and therapeutics (p. 14) that "Incalculable harm has been done by the common and convenient habit of writing prescriptions in hospital and dispensary practice by numbers instead of the ingredients." It must be granted that a student can learn but little of practical medicinal therapy by numbered or otherwise obscured medication.

A student cannot, after ten hours of instruction, learn to write prescriptions, but he can learn the general plan in that length of time. In conjunction with his course on principles of therapeutics, which should be given during the first half of the third year, the students should be repeatedly required to write prescriptions for drugs or preparations, as may be suggested by the drugs under consideration. They should write these prescriptions, as many at a time as seems desirable, and hand them to the instructor at the next lecture; he, later, should return them corrected to the students. It should be aimed to cover all of the common drugs by this method, the instructor advising the best method of administration and the amount required.

The students should also be taught to write prescriptions by the clinical instructors, both in the hospital and in the dispensary. It is only by this continuous personal instruction and personal criticism that a student will learn to write simple prescriptions of correct doses, to avoid incompatibilities, and to order the amount required for a given indication for a given patient. Also, very important, he will thus learn how it is best to order a drug, and how and when it is best for a patient to take the preparation.

He will also learn not to order too much or too little, or to order deliquescent drugs in powder or insoluble drugs in a liquid, or to order a minute dose of a drug in a powder or a large dose of a drug in a pill or capsule. He will learn how to write for ointments, liniments, ready made pills and capsules, and will learn how to use the Pharmacopœia. He can thus be taught to individualize his patient, and not to give the same mixture to every one who happens to have a cold, or a pain, in any other complaint. It should also be impressed upon the student to write legibly.

The better instruction given to the medical student in prescription writing throughout the third and fourth years, the less he will order unscientific pharmaceutical preparations when he is in private practice.

As Latin is not now a requirement for entrance into many of our medical schools, and consequently many medical students do not know Latin, it is not wise to attempt to teach them to write prescriptions correctly in Latin, and bad Latin is an abomination. It is better for a prescription to be written in abbreviated Latin as recommended by the Pharmacopœia, or even with English terms, such as water, peppermint water, wintergreen water, etc. The directions to the pharmacist should be in the usual Latin abbreviations, which the student should learn.

PRINCIPLES OF THERAPEUTICS.

Fifty hours should be devoted to this course, which should consist of recitations and explanatory talks based on a textbook. A brief review should be made of the useful drugs and their uses, based on a therapeutic classification and on their pharmacologic ability to meet the different indications. The valuable uses of the endocrine glands should be discussed; the various therapeutic measures should be described; the practical use of vaccines and serums should be discussed; diets outlined; various forms of physiotherapy briefly described; and instruction should be given in the treatment of chronic drug poisonings, chronic industrial poisonings, and emergencies.

Following is another quotation (p. 12) from the report referred to: "The Committee recommends unanimously and most emphatically that a thoroughly systematic and well planned didactic course in applied therapeutics or applied pharmacology be required. This should be directed towards teaching the principles and practice of rational treatment. It is therefore absolutely essential that the subject matter be arranged and presented according to pathological conditions and processes and not according to drugs. The committee again is unanimously and emphatically of the opinion that a course in therapeutics arranged according to drugs cannot be accepted as a substitute, and that any great amount of time devoted to such a course is largely misspent. Such a course places the emphasis in the wrong place and thus fosters a false and misleading attitude."

APPLIED THERAPEUTICS.

Some therapeutic teaching must be given by lectures or by book instruction, but the major part of this course should represent continual instruction at the bedside and in the dispensary. The instructor in applied therapeutics should carefully outline the treatment of a given patient, and in subsequent talks he should show the results (success or failure) of such treatment. The student should consider: the character of the contagion, if it is a case of infection, and the methods to prevent the infection of others (isolation, hygiene, care of all excreta); a specific antitoxin or antiseptic treatment, if such is available; the possibility or advisability of an attempt at abortive treatment; the treatment aimed at the lesion, if there is such, by local measures, drugs, or, if necessary, surgery; the amelioration of symptoms, by physical or medicinal measures, if treatment of such is indicated, such as pain, fever, cough, too high or too low blood pressure, heart weakness, hemorrhage, or the removal of effusions; the correction of disturbed functions, as evidenced by insomnia, delirium, coma, anorexia, flatulence, nausea, vomiting, constipation, tympanites, diarrhea, congestion of the kidneys, suppression or retention of urine, dryness of the skin, too profuse perspiration, evident disturbance of a ductless gland; the proper diet; and, during convalescence, a rearrangement of the diet, the administration of tonics, massage, or other physical therapy if indicated, and, if advisable, a change of climate.

The therapy should not be obscured by unlimited discussion of the diagnosis and of the pathology. In other words, the treatment of the patient who has the disease should not be relegated to oblivion. Even if he cannot be cured, his condition may be ameliorated and his functions and nutrition improved.

Constant emphasis, by the instructor in applied therapeutics, should be given to the physiological and biochemical processes which are disturbed by the disease which the patient has, and to the improvement that can be caused in the pathology of the disease. The condition of the patient's nutrition must always be kept in mind, and, also, how the disease affects his metabolism.

The student should be especially taught to seek all possible foci of infection: in the teeth, tonsils, sinuses, respiratory tract, gallbladder, gastrointestinal tract, appendix and genitourinary tract.

While most of this instruction is given the students in groups at the bedside clinic or at the dispensary clinic, very many disturbances of health, as well as many diseases, never reach the hospital or the dispensary, and instruction in the treatment of such must be given by didactic lectures.

PHYSIOTHERAPY.

It is not expected that, in the few hours suggested to be devoted to physiotherapy, a student could become at all fitted to administer these treatments. It is impossible, in the crowded curriculum for him to become expert in any specialty. The object today is to give him during his medical course a complete and perfected groundwork in the practice of medicine and surgery, and not a smattering of everything that is allied to medicine. However, he should not graduate without a knowledge of the value of all physiotherapeutic measures, and, also, an insight into the amount of study that is required to become expert in their application. If he decides to perfect himself in any one line of physiotherapy, he can take a postgraduate course under an expert to accomplish that object.

Exercise.—Two or three special lectures on this subject should be given, perhaps best by one of the instructors in the orthopedic department. But the value of exercise in certain conditions, and the harmfulness of overexercise in other conditions, should be taught in all of the clinical departments. A special elective course on the value of special exercises should be offered by the orthopedic department.

Massage.—Two lectures are sufficient to outline what can be taught didactically of this subject, and of the value of massage in general conditions and its special value in local conditions. As small as it seems, four hours of personal (each student separately) instruction and demonstration, best in the orthopedic clinic, is all the time in the curriculum that can be afforded to teach the student the actual physical workings of this form of physiotherapy. Few medical men will have the time or the inclination to do massage themselves. Also, an efficient masseur or masseuse is born and not made. In other words, not every man or woman who studies massage can become an expert, or will have the personality that will be acceptable to a private patient. In fact, for general massage to be successful, many times it is necessary to fit the operator to the patient, and an operator who is successful with one patient may not be successful with another. The value of massage should be taught the student throughout his clinical course.

Electricity.—Five hours of lecture and practical demonstration in the use of the different forms of electricity should be given the students as a class. Subsequently, each student should in turn be an assistant in the electrical treatment room of the hospital or dispensary for at least ten hours. He should not only be taught the value of the different forms of electrical treatment, but he should also be taught its limitations in therapeutic use. Examinations of paralyzed muscles should be demonstrated, and the value of the constant current, faradic, sinusoidal, d'Arsonval, high frequency, and diathermy should all be outlined and the practical application shown. Either in this course or in the course on radiotherapy, the value of heliotherapy and of quartz lamp therapy should be discussed.

X ray.—There should be four hours' demonstration of machines and technic of radiographic work and radiotherapy. The use of the x ray and radium for therapeutic purposes should be outlined and their limitations discussed. The value of and method of applying ultraviolet rays and the arc light should be described. Of course a student could learn but little, in the amount of time suggested, of treatment, of picture taking, or of the reading of the radiograms. There should be offered a postgraduate course in this very scientific branch of medicine, and coincidently should be offered a special course on regional anatomy. The seriousness of mistakes in picture taking and in reading of radiograms should be emphasized.

Hydrotherapy.—The outline of this physical measure should be taught in the course on principles of therapeutics. Therefore, one hour demonstration of an elaborate equipment, if such is available, will visualize for the student the methods of applying this form of therapy.

At some time during his course in the fourth year, or perhaps reserved for the first year of his internship in a hospital in such states as require hospital service before giving a license to practise medicine, the student should receive at least six hours of personal instruction in the methods of giving baths, sponging, douches, enemata, colon injections, the Murphy drip, and other methods. The young doctor should not begin the practice of medicine without a personal knowledge of the technic of these useful and necessary physical methods of treatment. He should know, when he instructs a nurse to administer these treatments, whether she is skilled or not. In other words, he should not leave these physical measures entirely to the nurse.

The use and value of the more elaborate hydrotherapeutic measures, mud baths, sulphur baths, steam baths, electric light baths, bakings, etc., can be learned only by a short internship in a hydrotherapeutic establishment.

Transfusions and other methods.—The textbook instruction on these subjects the student has already received in the course on principles of therapeutics. During the fourth year the students should be taught, in small groups, the technic of venesection, transfusion of salt solutions and of blood, hypodermoclysis, spinal puncture, aspiration, and similar procedures. Of course, during his internship in a hospital in his first postgraduate year the student should not only be the personal assistant in such operations, but should, under instruction, do these minor operations himself. It is not intended or supposed that every medical graduate could become skilled in the technic of the transfusion of blood or of salt solutions, or even perhaps in the technic of spinal puncture, as it is much better for a few physicians or surgeons to specialize in this work; but emergencies may occur in the life of every physician when it may be necessary for him to avail himself of the technic learned in the hospital.

PSYCHOTHERAPY.

Four or five lectures on this subject would seem sufficient for the undergraduate course, and they should be given in the latter part of the fourth year. Psychoanalysis and psychotherapy can only be well studied as a postgraduate elective, and then, like nursing and massage, only a certain number of medical men are fitted to handle this subject properly.

A working knowledge of this branch of medicine is essential, as well as is a good working knowledge of the disturbances of the endocrine glands. The better these subjects are understood and the more the patient is studied from the whole biological and metabolic standpoint, the more rapidly will treatment of his disturbances be successful, and fewer operations will be done. The undergraduate student should, however, be told that psychoanalysis is frequently overdone and is being utilized in quackery. While the study of mental attitudes, of nervous reflexes, of memory disturbances, and of vegetative and vagotonic symptoms are valuable in this neurotic age, it should not be forgotten that sometimes stopping the coffee or tea, or extracting a tooth, or doing some other simple thing may stop the symptoms and restore the patient to health.

OCCUPATIONAL THERAPY.

This is also a postgraduate study, but two or three lectures can well be given the medical student in the latter part of the fourth year, to interest him in this subject and to show him what is being done in this restorative branch of therapy. Illustrated lectures are very valuable to bring this work graphically before the student.

A Social Service Ward for Women and Children*

A Solution of the Family Problems of Venereal Disease

By VICTOR COX PEDERSEN, A.M., M.D.,
New York.

No hospital can do its duty unless it has beds for venereal disease patients. This term includes those who have had infections and still have them in communicable forms so as to require treatment and those who have had the infections but may not remain menaces, yet demand exact diagnosis of their status. These two groups comprise the class of disease acquired by voluntary sexual relations or innocently acquired by involuntary, commonly nonsexual contact. The term acquired disease suggests its antipode hereditary disease as a great question. There is no more important and difficult problem than the results of syphilis and gonococcal infections. The importance rests on social, economic, moral and medical grounds. The difficulty lies in the hapless attitude which the community too often persists in toward all aspects of the problem.

The social importance is found in the disastrous and disqualifying results in the patients and in society. Finances determine late marriages almost until the years of normal sexual functions are decreasing. Underpayment of the working and salaried classes results in bare subsistence for the earner himself and no worthy subsistence for the home. The false teaching that our sexual organization and its normal expressions are sinful leads to shame, hypocrisy and false pretense.

It is a reasonable viewpoint and one which may be defended, that the social elements of the problem are distributed a third to the male, a third to the female, and a third to society. Each of these three parties has its own mistakes and responsibilities. It is in human experience likely that they equal each the other in all relations and interdependence.

The economic importance devolves upon the fact that these diseases incapacitate both sexes and all ages during their acute stages and in their chronic periods may disable. Statistics in the military service are reliable, because the patients are under control. The average navy has in its hospitals the equivalent of the crew of a second class battleship. These diseases in the civil community equal them in the military service beyond reasonable doubt only the statement cannot be proved with equal clearness. These are the quantitative economics of veneral disease.

The qualitative determinations are the following general data. The major complications of gonococcal infection in the sexual glands of both sexes often sterilize. A very large number (about fifty per cent.) of operations on women for abscesses of the tubes and ovaries are due to this infection. Very many childless marriages are due not to sterile women but to men rendered sterile by gonococcal involvement of their testes and vasa deferentia. No longer are women subjected to stretching and curetting operations until the husband has been shown to be normal. Many women have nondevelopment of the womb with consequent sterility due to infection in babyhood or childhood. These devastating infections lead to arrested development and the abnormality of a child's uterus in an adult.

The moral importance is a subject by itself and requires little deep consideration for realization of its just measure. No ordinary words express the misfortune to society produced by those teachings which make human sexuality the object of contradictory viewpoints. The natural estimate is the sound one in realizing that sexual procreation is the real basis of plant and animal life. There is no other plan in the higher orders of creation. No other reproductive physiology is vouchsafed to man, hence the sexual method should be dignified and not degraded. The law of sexual relation is probably universal. Even in the lowest creatures which multiply by division, it probably exists in prototype just as these same creatures have muscular, nervous and digestive functions all in primordial degree, but sufficient to provide motion, sensibility and nutrition under our microscopes.

The artificial viewpoint as to sexual relations is a moral misfortune, because it sets up the proposition that those who are celibates are virtuous, although they really defy biological laws, whereas those who in obedience to biological laws live in normal sexual relations are less virtuous. This is the teaching of religious extremists and it has done more harm than good in the question. It is the moral extreme. It is the action which underlies the equal and contrary reaction of the mental and moral attitude of more or less utter laxity in the matter. This is the immoral extreme antipodal of the foregoing moral excess. Between these wide apart limits lies the middle ground that the law of life about us, which knows no great exception, is also the law of life for us and should not be disregarded or maligned.

With these bases, or axioms, a few words are permissible as to the scope of diagnosis and treatment work among the various classes of cases met in families and groups of the community. There is no doubt that farreaching good to the patients, the families and the community would ensue if every large community would have ward service for venereal men, women and children. In a city of ordinary size wards of ten beds each for men, women and children could be kept full and even have waiting lists. The foundation fact is that when syphilis has been discovered in one member of a family, all others in blood relationship or contact had best be examined. If this is not done, then many important cases will be missed and not treated. As an illustration, in a family in my practice the father died of cerebrospinal syphilis; the mother has the disease in a state of incomplete cure, the elder daughter has positive blood and spinal fluid tests and is receiving adequate treatment as far as her own ignorance and obstinancy

---

*A contribution dealing with the economic and sociological sides of this problem and ward service will appear in the April issue of the *Journal of Social Hygiene*.

permit. The other children have negative blood and spinal fluid tests and have probably escaped the hereditary disease but must be watched. For such a group ward beds alone give the necessary facilities for detail and finality of diagnosis. Another family is that of a man infected for nearly twenty-five years. He had been treated with almost full success according to the established procedures of that epoch. I examined and found free of syphilis his wife and five children, yet he died of syphilis of the heart and arteries. Ward service alone is fitting for the study of these obscure and highly important cases.

With similar cases in great number in hospital and private practice and cited in medical literature in mind, a Social Service Ward for Women and Children was begun at St. Mark's Hospital in New York City in July, 1922. It is the purpose of this paper to note the plan, scope and results of the first three months of service.

For the benefit of any other hospital which may be contemplating the opening of such a service and which, like St. Mark's Hospital, has a social service group, it is well to note that whereas the ward is of, in and for St. Mark's Hospital it is temporarily independent of the hospital finances because the Social Service Committee and its friends meet the expenses. All accounting is kept separate as a temporary expedient and the plan is more easily developed and modified. Several private citizens on hearing of meritorious cases have given financial support. The average person is interested and will give generously to the cause if he understands the need of sound financial underwriting. It is intended to give this project an organized trial for two years, possibly three years. Of this period it has taken inevitably six months to detail the best management of the applications, admissions and discharges of the patients. The balance of the first year will pass in determination of the methods of dealing with the patients after admission and during their sojourn in bed. These questions have been fairly well settled but there are refinements and improvements.

The actual accomplishments during the first ninety days have been suitable announcements of the work to institutions, agencies and persons and the acceptance of practically all patients referred. With hardly an exception each bed has been filled all the time and a waiting list has existed either directly or indirectly.

Twenty-nine patients were received and fully diagnosed, and then returned for treatment to the agencies from which they came, or were referred for treatment to the Clinic of St. Mark's Hospital. Their case reports are classified into syphilis, gonococcal infection, nongonococcal disease and miscellaneous venereal cases. Each group will be discussed in the order named. Further classification is indicated as each group is considered.

SYPHILITIC INFECTIONS.

The syphilitics are subdivided into suspected syphilis, established syphilis (independently of the clinical stage) and congenital and hereditary syphilis. The chief point is to keep together the patients of each group and subdivision, first in disease relations and second in numerical sequence, although the plan fails to observe the numerical order of admission. Suspected syphilis numbered four. In the diagnosis of syphilis lie two principles. If the patient has or has had the disease he himself and his physician must know the fact and the degree of the disease. In no other way can the patient be induced to submit to and the doctor plan for right treatment. If the patient has not and has not had syphilis he himself and his physician must know this fact. In no other circumstances will the patient be relieved from fear of the disease and the doctor from ordering unnecessary treatment. In the Social Service Ward care has been taken to observe four essentials: 1, A good record of the patient and his civil connections (mate in marriage, children, parents, brothers, sisters, etc.); 2, a complete physical examination with special reference to signs and stigmata of syphilis; 3, a full laboratory investigation including the blood and spinal tests, and, 4, the results of active treatment or of the temporary arrest of treatment. The following notes of the cases are epitomies for the sake of omitting medical detail which might be wearisome.

CASE I.—Diagnosis, suspected syphilis. E. F., twenty-one years old, married, no occupation, born in the United States. Admitted on July 8th, discharged on July 12, 1922, improved. Her husband, with locomotor ataxia, could not be reached for tests. It, therefore, became essential to admit and examine the woman, because, if syphilitic, the mother would have to have active treatment to control the disease in her unborn baby. As an applicant for a maternity hospital every test was performed. No gonococcal infection was found. The Wassermann blood test by the maternity hospital was strongly positive. Another by a private laboratory was less positive and a third by the Department of Health was negative. This confusion of tests required admission and study. The Wassermann test of the blood was mildly positive, almost negative, while the spinal fluid was negative. This woman was made an observation case and referred to one of the maternity hospitals for control and confinement. If it is shown that she did not have syphilis has not the work been well done? If observation proves mild syphilis, without effect on her spinal fluid, are not the relief she will obtain and the protection her baby will receive ample reward? Jeans (1) found 85.9 per cent. of mothers of syphilitic children to have positive blood tests and several mothers to show old signs of syphilis although their blood tests were negative. The unborn child will be benefited or cured if treatment is given during pregnancy.

CASES II and III.—Diagnosis, suspected syphilis. S. R., twenty-eight years old, housewife, born in the United States, admitted, with infant son, and discharged October 5, 1922. There was probably syphilis in this family. The blood test had been ++ on September 14, 1922. The woman and her infant were admitted for spinal puncture. The woman refused treatment or examination and left the ward promising but finally refusing to return. Refusals of cooperation are not uncommon among the ignorant, particularly if the source of the infection—husband or wife or both—has been pronounced "all right" or it is desired to hide the facts. Two per cent. of the patients refuse but they thereby remain probable menaces. The law does not reach them unless they have open lesions and are actual menaces. The mother and sisters of the woman have a history of syphilis. This patient is in reasonable health but probably has late hereditary syphilis.

What refusal of diagnosis and treatment may lead to is contained in Case 73 of Solomon and Solomon's *Syphilis of the Innocent,* as follows: "Case 73. The father and mother had 'sores,' probably chancres, which received local treatment only. Their first child was stillborn and the second child died of hemorrhage of the cord. Before the death of the second child, the parents reported for treatment but refused to continue it. Two years later their fourth child was found to be syphilitic. The third child had died at the age of three weeks. When the diagnosis was made on the fourth child and treatment instituted, the parents agreed to systemic treatment themselves. How much better if they had done this earlier. One always has to reckon with the individual equation. Education and efficient followup are necessary in these cases."

The cases of established syphilis comprised eight patients.

Case IV.—Diagnosis, syphilis, first and second stages. M. O'R., thirty-three years old, divorced, factory hand, native of Ireland, admitted July 15th, discharged August 2, 1922, improved. Married thirteen years ago, separated from her husband four years. She had had five pregnancies; three of the children died in infancy and the other two later. Denied sexual irregularities. Four weeks before admission she attended a party at which she became dizzy and unconscious through wine and dancing. On the day of admission she noticed a generalized eruption on her forearms and body. Typical secondary eruption and a small chancre in the vagina were present. Wassermann blood tests were strongly positive. As this woman worked in a food factory her disease was fully controlled before she was discharged from the hospital, in accordance with regulations of the Department of Health.

Case V.—Diagnosis, syphilis. G. A., thirty-seven years old, married, native of Norway, housewife; admitted July 24th, discharged August 11, 1922, improved. Married three years before admission, two pregnancies, the first ending in miscarriage. While in quest of employment, examination of the blood discovered syphilis. The skin was undoubtedly syphilitic. Lymphatic glands were enlarged. In the child, born before the mother became infected, all tests were negative. Very strongly positive blood tests in the mother were obtained on July 24th and August 9th. Under continuous intensive treatment the activity of the test was reduced by half. Rapid control of the disease protected not only the employers in the future but also her baby in the present. Hence a real economic question was properly settled. As she might become a nurse for children full diagnosis for gonococcal infection was performed and no signs were found.

Case VI.—Diagnosis, pregnancy and syphilis. H. S., twenty years old, born in the United States, no occupation; admitted July 26th, discharged July 27, 1922, improved. For about two years had been a common law wife and contracted gonococcal infection about a year before admission. The patient remembered a small sore in her vagina which disappeared after two injections of salvarsan. She had been pregnant nine months and delivery was due about the fourth of August. Wassermann blood test was very strongly positive. One dose of salvarsan was given on admission. The immediate onset of labor made it necessary to transfer her to Bellevue Hospital where the care and housing of infectious syphilis are more feasible than in a small institution.

Cases VII and VIII.—Diagnosis, syphilis. M. S. and baby. The mother was twenty-two years old, a laundress, born in the United States; admitted August 4th, discharged August 16, 1922, improved. This woman was delivered at a hospital, where the Wassermann blood test was positive. The general history and condition of mother and child were negative. She was referred to the ward for decision as to syphilis for her own as well as the baby's sake. The examination of both patients was negative. A control Wassermann test of the blood was again strongly positive and that of the spinal fluid was negative. It was safe to treat the woman as syphilitic for a brief period as a further test and as a protection of the baby. As the child developed slight irritation of the eyes the mother was fully examined for gonococcal or nongonococcal suppurative infection. Nothing was found by the laboratory which was corroborated by early recovery of the eyes. These patients removed to Pennsylvania, with instructions as to continuing the treatment there. The social importance is the observation and treatment diagnosis of the mother for her baby's sake as well as her own. As the child was so well it was considered unnecessary to subject it to the tests for syphilis until after observation and treatment of the mother. Physical examination did not reveal syphilis. Removal from the city obstructed final analysis.

Case IX.—Diagnosis, syphilis of the nervous system. L. J., thirty-two years old, married, white, housewife, born in the United States; admitted September 1st, discharged September 14, 1922, improved. This woman was infected about fifteen years ago. She had had one miscarriage. She had constant headache, which meant probably a low cerebral meningitis. The muscles of her eyeballs were partially paralyzed so that she was walleyed and her eyeballs bulged unnaturally. The woman was treated energetically at the reformatory so that tests of her blood and spinal fluid were more favorable than would otherwise have been the fact. Examination of the eyes showed that their refraction was still good. The importance of the case lies in controlling the syphilis and the paralysis of the eyes and the meningitis, thus preventing mental breakdown. The immediate response to treatment was only partial; unfortunately after discharge she discontinued treatment.

Case X.—Diagnosis, gumma of the leg. A. F., twenty-seven years old, married, housewife, native of the United States; admitted September 6th, discharged September 21, 1922, improved. The woman had had a profuse discharge from the vagina for years, even during her childbearing. No infection of gonococcal or nongonococcal type was proved. The husband was under treatment at a clinic and the wife had had a few doses of salvarsan but no regular treatment. There had been nine pregnancies, one miscarriage, two children dead. Three children were found to be free of syphilis. Although the tests of blood and spinal fluid are important diagnostic means, negative results in each of them, even when taken at the same or different times do not exclude syphilis. The diagnosis may be complete as in this case by such signs as gumma. Judgment is required to bring into relation general and local symptoms and all laboratory findings.

CASE XI.—Diagnosis, syphilis, third stage. C. C., forty years old, married, housewife, United States; admitted September 22nd, discharged September 24, 1922; improved. This woman is making a fight against locomotor ataxia. She has been a patient of the Urological Clinic for many years and her condition is improving. She has been receiving intraspinal treatments. The Social Service Ward cannot do higher work than study to guide the treatment in such cases or to aid her to keep body, soul and home together.

Syphilis descended from parents to children is now classified as congenital (if infection occurs *in utero* directly) and as hereditary syphilis (if without direct infection *in utero* the child's development is impaired). Nonne (2) regards congenital syphilis as the preferred scientific term. There were four patients of this type admitted.

CASE XII.—Diagnosis, syphilitic cerebral epileptiform seizures. A. B., seventeen years old, single, packer, born in the United States; admitted July 27th, discharged August 11, 1922, improved. Since about her seventh year she had had convulsions with unconsciousness lasting an hour and accompanied with biting of her lips. These seizures did not begin in any one part of her body and gave no special warning. The child asserted that the landlord of her home forced her when she was about eight years old. She did not remember any result of this attempted intercourse, such as a sore or a discharge. If she was then inoculated with syphilis it was unlikely that the seizures would have begun at the same time, if they were due to syphilis. It was likely they were due to hereditary syphilis. The examination of this girl by the Department of Nervous Diseases excluded hysteria and true epilepsy. Hence there was added reason for regarding the case as syphilis of the nervous system. During one of these seizures she fell on the street and was taken to a hospital where her blood Wassermann was found positive. This was the first lead to her condition. One obstacle in all this work was met in this family. Both the father and mother refused to have their blood tested and each violently accused the other of having acquired the disease. There was no moral doubt of guilty knowledge in one or other parent. Likewise the brothers and sisters refused to be examined. Hence the complete line of family data could not be ascertained. Such obstruction to service by families is disappointing but we must pardon the errors of ignorance.

The bearing of syphilis in the parents upon the children is demonstrated by Case 54 of Solomon's recent work. "Case 54. Mrs. W. was informed that she had syphilis when she was twenty-three years of age, but neglected treatment. She bore five children. The oldest had poliomyelitis at two years. The second at the age of nineteen was unable to walk normally, was sullen, morose and unwilling to work. The third boy at the age of eighteen was weak and sickly. The fourth child had been under antisyphilitic treatment for five years but had not thriven. She was about fifteen years of age, nervous, excitable, moody, easily depressed, and high tempered. The fifth child died immediately after birth. The relationship of syphilis in the parents and psychoneurosis in the children is interesting."

CASES XIII and XIV.—Diagnosis, suspected hereditary syphilis. G. F., four years old; M. F., six years old, white, born in the United States; both were admitted August 31st, and discharged September 2, 1922, improved. The father had had syphilis; on November 8, 1920, his blood was strongly positive. Since the father was a syphilitic, the wife and the children themselves and the community at large had the right to demand that the status of the whole family be diagnosed and, if they too were syphilitic, that they be treated and cured. The physical examination and blood tests of both children were negative. In order to rule out error and to protect the other members of the family the remaining four children were examined as clinic patients; four boys aged eight, ten, twelve, and fifteen years. All were negative. From these data the conclusion is reasonable that the father—if infected—acquired the affliction after the birth of the youngest child. False economy might indicate that so much work in a whole family in search of possible infection is misspent effort and time or that it would save money to wait for signs of the syphilis in the unfortunate member or members of the household who had in fact inherited the disease. Is it not better sociology to prevent late syphilis in brain, spinal cord, eye, ear, liver, etc., than to treat it after it is deeply seated and probably no longer remediable?

CASE XV.—Diagnosis, hereditary syphilis. A. S., eight years old, school child, born in the United States; admitted September 11th, and discharged October 16, 1922, improved. For two years she had had painful periostitis of the right shin and for a few months she had had similar symptoms in her right elbow joint. The skin over these regions had never broken down. The nose and teeth presented further proof of syphilis. Although the opposite leg was not painful it showed signs of syphilis also. The x ray pictures showed syphilis of bone distinctly. The Wassermann test of the blood was strongly positive and completed the evidence. Fortunately the child had no kidney disease due to her syphilis and no vaginal infection. While in the hospital she developed a peculiar cold. Tuberculosis was ruled out. Active syphilitic treatment was begun, her tolerance for the medicines and comprehensive methods of helping her were established for the staff of the clinic or of any other hospital. Plain duty was done when the older child was examined. It had no syphilis because the parents had not become diseased before it was born. Hence the second problem in this family case was answered and very happily answered. The mother was syphilitic as was proved both by the state of her blood now and by the fact of her syphilized child already detailed. The decision of family problems like these is high science and economics.

GONOCOCCAL INFECTIONS.

In sexual infection the discharge may have the gonococcus or an allied organism acquired sexually or accidentally and innocently. Its actual source may never be known. Of innocent patients the following three are examples:

Case XVI.—Diagnosis, gonococcal infection; abnormality of the hymen. A. C., twelve years old, school child, born in Austria; admitted August 12th, discharged September 9, 1922, improved. This child was respectable and never had had bad habits or companions. There was no possibility of intercourse because the hymen was not only not torn but also not normal and thick. No cause of the infection could be determined. The disease was true gonococcal invasion. She was kept under treatment until all symptoms abated, then discharged after instruction of the mother as to home treatment and regular dispensary care. When the tests indicated absence of disease the girl was allowed to return to school. The cure must be absolute before sexual maturity is reached. An operation was done correcting the child's sexual anatomy so that she is now normal. In having relieved the infection a service has been done, the value of which she will never realize. For example, she will never have infantile uterus or degeneration of the mucosa or disease of her tubes and ovaries, thus leading to sterility.

Case XVII.—Diagnosis, gonococcal infection following rape. E. C., eight years old, school child, born in the United States; admitted August 15th, discharged August 31, 1922, improved. The mother noticed a vaginal discharge for which she took the child for examination. Smears and cultures showed the gonococcus and suitable treatment was begun, first, to prevent other invasion, and, second, to cure the child. Neither father nor mother had any sexual affliction. A youth boarding with the family and sleeping in the room next to the child's had undoubtedly attempted congress with her. This youth was known to have gonococcal disease. He was arrested, and convicted.

Case XVIII.—Diagnosis, gonococcal subacute infection. J. P., four years old, born in the United States; admitted September 1st, discharged October 4, 1922, improved. This child's father is in the army, her mother is dead and her aunt is a professional nurse. With her father usually away and her aunt out on casework the little girl is at great disadvantage. No source of the infection could be ascertained. Female children acquire infection of the sexual organs with organisms of diarrhea and it is a sequel of scarlet fever, diphtheria, measles, typhoid fever, influenza, and almost any severe infectious disease. The child had had none of these, but was the victim of constipation and diarrhea. The aunt could not say whether the inflammation of the sexual organs began after diarrhea or not. It therefore was important to decide the type present. Perhaps as recently as five years ago the majority of physicians assumed gonococci to be present in any little girl having discharge from her vagina. One may not utter such an accusation now unless a smear and culture have proved the gonococcus to be present. The gonococcus was found. The source of the infection could not be ascertained. Regular treatment was given until examinations were negative. Although the service of the ward is basically diagnostic and preventive, continued treatment was pursued because the vocational conditions of both her father and her aunt prevented sufficient home care. Gonococci had disappeared by September 19th. Treatment was continued until October 2nd when she was discharged and thereafter followed up at the clinic and home. In this way precautions against relapse were taken. The importance of early cure lies in the fact that if the gonococcus penetrates the womb of immature girls its destructive results are certain to arrest development and sterility ensues.

Case XIX.—Diagnosis, gonococcal infection. A. D., fifteen months old, born in the United States; admitted September 26th, discharged October 24, 1922, improved. The baby manifested profuse discharge from the vagina about one month before admission. The cause could not be ascertained. She had been sent to a summer camp in perfect health and had returned with the discharge. Examination showed redness, swelling, tenderness and discharge. The gonococcus was in the smears taken and treatment was begun at once. Under this treatment the germs disappeared quickly. The tests on October 7th, 20th, and 23rd, were shown free of the gonococcus. The child was referred to the clinic for observation and cure of the secondary catarrh.

NONGONOCOCCAL INFECTIONS.

Potentialities for ill of infection of the urinary and sexual organs are great. It is essential that every discharge shall be settled as to its character. If it is nongonococcal it must be determined as to its innocuous or nocuous tendencies. These broad axioms need mere mention for the medical reader. Of the nongonococcal cases the following seven records are very instructive:

Case XX.—Diagnosis, pregnancy; nongonococcal vulvovaginitis. E. M. P., twenty years old, single, born in the United States, no occupation; admitted July 15, 1922, discharged July 24, 1922, improved. She became pregnant in January, 1922. She thought that the father of her baby had no venereal disease but about the second month of her pregnancy a discharge developed. Smears and culture showed no gonococci. This girl was treated until the diagnosis was settled and she understood how to care for herself, and was then referred to the prenatal clinic. Four all important things were accomplished. The woman and her mate were cleared of the suspicion of venereal disease. She was proved to be a safe inmate of a home and she was protected against infection in childbed and her baby was safeguarded against infection and destruction of its eyes. She was delivered on July 29, 1922, in St. Mark's Hospital and made a perfect recovery.

Case XXI.—Diagnosis, suspected gonococcal infection. F. E. and baby. The mother was seventeen years old, housewife, from Bohemia; admitted August 19th, discharged August 28, 1922, improved. A baby was born to this girl after a common law marriage with a young man who at first ran away but later returned to marry her. A discharge developed from the vagina such as is very common during the nursing period. Upon going to a hospital for examination and treatment the opinion was given (seemingly by a nurse or through a confusion of specimens) that she had true gonococcal infection. This news reached the young man who refused to marry her if this diagnosis were correct. With marriage as the proper solution of misalliance, this socalled diagnosis at once assumed grave importance. Smears and cultures on two different occasions were made. No gonococci were found and the girl was freed of suspicion. The laboratory report was confirmed by the facts that the disease had not extended to her tubes, ovaries and peritoneum and the eyes of the baby had not become infected.

CASE XXII.—Diagnosis, nongonococcal infection of the vagina and womb. E. G., twenty-two years old, married, housewife, born in the United States; admitted September 20th, discharged September 27, 1922, improved. There was venereal infection in the husband before his marriage but little evidence of it at the time of marriage. The fact that she had had two children at close intervals was prima facie evidence that she had not become infected. A profuse discharge suggested disease to the woman and she knew enough to be suspicious of her husband. Such facts lead to quarrels, disrupted homes, sometimes murder. The ward is for such patients and she was given intensive examination. The blood test was found negative and syphilis was ruled out. Smears and cultures showed no gonococci. The discharge was due to simple organisms which a little treatment would destroy. She was improved by a week of treatment, taught the treatment herself and discharged in care of the clinic. Her confidence in her husband was restored.

CASES XXIII and XXIV.—Diagnosis, suspected gonococcal vaginitis. M. G. and baby. The mother was twenty-seven years old, single, did housework, born in Ireland; the baby was a male, ten days old; admitted October 6th, discharged October 10, 1922, improved. This woman passed through a normal childbirth late in August, and remained well until she contracted influenza. With little disturbance of her health by the influenza, pain in the lower parts of her body began, followed by a profuse vaginal discharge. The nature of the discharge and the pain became grave. If the discharge was only a sequel of influenza, it might be relatively unimportant, although actively infectious. If the discharge was gonococcal, then in any nursing or other home her presence could not be tolerated. What concerns the woman in the latter condition would be the extension and damage to the uterus, tubes and ovaries with consequent unsexing. Examination of the child showed no infection of the eyes, genitals or bowel with the gonococcus or any other germ. Smears and cultures from the mother showed absence of gonococci and other important organisms. In the four days of her ward care she was taught how to protect her baby against infection and how to care for herself.

CASES XXV and XXVI.—Diagnosis, nonvenereal inflammation of the vagina. R. S., and infant son. Mother was twenty-four years old, single, servant, born in the United States; admitted October 11th, discharged October 26, 1922, improved. This mother had been at a home for some time since her delivery. A profuse discharge from her vagina and severe pain in her right side had appeared. The questions were concerned in the kind of infection, its relation to the pain and cause of the pain. Smears and cultures showed that she did not have gonococcal infection but that germs were present which often went with infected kidneys. Examination of the bladder with the cystoscope, and the taking of specimens separately from each kidney and an x ray examination showed her to have a small stone in one ureter near the bladder. This stone came away without operation and was lost by the patient. Meanwhile suitable measures improved her other sickness. The woman was discharged improved and free of all fear that she had acquired venereal disease, which had ascended into her tubes and ovaries and was causing her pain.

MISCELLANEOUS CASES.

Patients who belong to the urinary or sexual groups in a miscellaneous classification will apply for and be entitled to diagnostic and preventive investigation. Many are as important as the venereal cases and fully as difficult.

CASE XXVIII.—Diagnosis, hysterical retention of urine. J. C., seventeen years old, single, no occupation, a Pole; admitted July 27th, discharged August 21, 1922, improved. In another hospital appendectomy had been performed about five months before admission. During convalesence her urine was drawn. By hysteria the child acquired the notion that she could not urinate herself. For five months her mother had been drawing her urine three or four times a day. It became necessary to rule out hereditary syphilis as a cause of her nervous breakdown or any local infection of the sexual or urinary organs, both as the cause of the bladder difficulty or as the result of the use of the catheter. The actual condition of her nervous and mental systems was also important. Careful examinations for syphilis and for sexual infections were negative. The interior of the bladder was shown to have been irritated but not seriously damaged by the catheter. Her nervous system was found to be below high grade but not greatly defective. It was easy after these analyses to benefit the girl and to discharge her convinced that she could pass her urine naturally.

CASE XXIX.—Diagnosis, oversexual excitability; masturbation. F. D., four years old, born in the United States; admitted October 20th, discharged October 23, 1922, cured. This little girl had been detected in selfabuse. The future could hold only sexual temptations, then excesses, and finally degradation. A minor operation was done corresponding with circumcision in the male making the parts normal and no longer the cause of selfabuse. About two months after this girl was discharged, the nurse in charge of her at a home reported that all masturbation had disappeared.

This work has already extended sufficiently to indicate its need, scope and results, and also sufficiently to justify its development, endorsement and support. Within ten years every well organized community will insist on similar solution of its venereal disease, social problems and similar management of its citizens who are the factors in these problems.

Synergistic Analgesia in Rectal Operations*

By J. F. SAPHIR, M.D.,
New York,

Consulting Proctologist, Manhattan State Hospital; Visiting Proctologist, People's Hospital, Home of the Daughters of Jacob, Home of the Sons and Daughters of Israel; Chief of Rectal Department, Stuyvesant Polyclinic.

General and local anesthesia of all kinds and varieties have been used in rectal operations, with a certain amount of comfort and safety to the patient and with a greater or lesser degree of success, depending upon the kind of case and the anesthetic that is used. General anesthesia in rectal surgery is the anesthetic of choice, except in those cases where it is contraindicated, as in renal, cardiac or pulmonary diseases, or in those cases where a general anesthetic is refused or where the case is one in which the operation can be successfully performed upon under local anesthesia. The great majority of rectal operations can be thoroughly and successfully performed under either local or general anesthesia.

The only excuse that I have to offer for advocating the use of synergistic analgesia in rectal operations is that there are a certain limited number of cases that crop up in the practice of every proctologist, where the patient's heart, lungs or kidneys will not permit the conscientious rectal surgeon undertaking an operation under the influence of a general anesthetic, and yet on account of such other conditions as an extensive ischiorectal abscess, with numerous discharging fistulæ, it would be inadvisable to use a local anesthetic, for fear of spreading the infection when injecting the solution, yet these patients require and demand immediate relief; or, where the patient has been bedridden as a result of some other systemic disease or illness, and a rectal condition develops that requires operative intervention, and the patient, or his relatives and friends, refuse to permit the use of any anesthetic local or general. In general surgery and in head surgery, these objections have in a great measure been overcome by the use of the high colon oil ether anesthesia. But in rectal cases this method has not been feasible, on account of the necessity of working in and about the anus and rectum. The reciprocal augmentation of the action of one drug by that of another constitutes synergism.

The late Dr. Meltzer, in reference to the synergistic action of magnesium sulphate, expressed himself as follows: "When after the administration of an amount of ether, insufficient to cause anesthesia, an inefficient amount of magnesium sulphate is injected intramuscularly, a profound anesthesia follows which can be maintained for several hours" (1). Meltzer was the first to introduce magnesium sulphate as an anesthetic agent, but he endeavored to produce the desired effect without morphine.

Dr. J. T. Gwathmey (2) reports experiments in conjunction with Dr. E. J. Pellini, to the effect that "a sufficient number of animal experiments had been conducted to prove that one eighth grain of morphine in two c. c. of a twenty-five per cent. solution of chemically pure and sterilized magnesium sulphate, given hypodermically and repeated twice at half hour intervals, anesthetized an animal sufficiently for the full force of an artery clamp to be placed anywhere on the skin without being noticed by the subject."

It is important that the chemically pure magnesium sulphate should be used. Meltzer (3) found: 1. The hypodermic injection is painless. 2. By using a twenty-five per cent. solution, complete anesthesia, including relaxation of all voluntary muscles, may be obtained with subsequent full recovery in animals. 3. The subcutaneous injection of magnesium sulphate does not produce immediate or late diarrhea, but the salts are eliminated by the kidneys. 4. No irritating influence was found among the effects of the use of these salts. The more concentrated the solution the more rapid the effect. The danger of anesthesia by magnesium sulphate comes only from respiration, but this can be completely reversed by the injection of a small quantity of calcium salts. The heart and pulse remain normal.

From these data it will be seen that magnesium sulphate is a safe agent to produce anesthesia but is not as valuable when used alone as when used with other agents. When used synergistically with other drugs, such as morphine, it is absolutely harmless and one of the most effective agents we know. With the use of three hypodermic injections, each containing an eighth of a grain of morphine and ten c. c. of a twenty-five per cent. chemically pure and sterilized magnesium sulphate solution, given at twenty-five minute intervals, the last injection given about half an hour before operation, the patient will be relieved from pain during the operation and be free from postoperative pain for twelve to twenty hours. In hypersensitive patients this method of analgesia may be supplemented with a little nitrous oxide and oxygen.

Gwathmey (4) reports that shock is absent, the patient is not in the third stage of anesthesia, there is no lowering of blood pressure, pain is absent for a longer time than when general or local anesthesia is used, usually for fifteen to thirty hours. The patients are comfortable, without nausea or vomiting, and the pulse and temperature are normal.

Magnesium sulphate has no deleterious effect on any of the tissues or organs of the body, and when used synergistically has no toxic effect whatever on the respiratory centre. It seems to act mechanically with morphine, holding the drug in contact with the tissues longer than when used alone, but with ether or gas and oxygen it acts by deepening or increasing the effect rather than prolonging it. An eighth of a grain of morphine in two c. c. of twenty-five per cent. solution of magnesium sulphate is increased in value fifty to one hundred per cent., compared with the same amount of morphine when used in sterile water.

One hypodermic of this mixture will relieve pain from ten to thirty hours, as compared with two to four hours with sterile water. When magnesium sulphate is used with ether, one third the quantity of ether is necessary; when used with nitrous oxide and oxygen, the oxygen may be increased and the nitrous oxide decreased. One hour and fifteen minutes before operation the first hypodermic of one eighth of a grain of morphine and ten c. c. of a twenty-five per cent. magnesium sulphate solution is injected and repeated at twenty-five minute intervals for three doses. If any idiosyncrasy is present it will manifest itself before the third dose is due. By the addition of magnesium sulphate to the preliminary morphine injection, better relaxation is obtained, and nausea and postoperative pain are much reduced if not entirely eliminated.

---

*Read before the American Proctological Society, at the annual meeting held in St. Louis, June, 1922.

Cushing (5) asserts that "the peripheral muscles and nerves are unaffected by morphine in any but overwhelming doses," yet when used with a twenty-five per cent. solution of magnesium sulphate the synergistic action of one upon the other holds in abeyance the extreme pain, operative and postoperative, even about the very sensitive anus and rectum.

The possible explanation of the increased action of morphine may be that the magnesium sulphate holds the morphine in contact with the nerve tissue longer than the morphine can retain that contact alone, and that the combined acion, or result of synergism is safer and at the same time more powerful than either of the drugs when used alone. The postoperative wound pain is eliminated, the patients are carried through the pain zone easily and comfortably, without any further administration of morphine. I have also noticed that postoperative catheterization was unnecessary, on account of the greater amount of relaxation produced by the use of synergism. The appetite is also better on account of the absence of gas and pain, which means a shorter convalescence.

Analgesia or the reciprocal augmentation of the action of one drug upon another is still slightly understood, but the results are greatly in its favor as compared with any other form of anesthesia.

Morphine and magnesium sulphate give relief from pain either immediately or at any other time for a much longer period of time than morphine alone.

CASE REPORTS.

Case I.—Mrs. E. B., aged fifty-four, was referred to me by Dr. I. Reissman, September 12, 1921. This was an extremely bad cardiac case, the patient suffering from myocarditis, endocarditis and pericarditis. She was in such a bad state that after she had alighted from the taxi and walked a distance of not more than ten or twelve paces into my office, she collapsed from the exertion and it took me about fifteen minutes to resuscitate her. She had a pale, waxy look, was very anémic, was gasping for breath, and wore an anxious expression as if suffering severe pain, and from great loss of blood. She gave a history of having had piles as long as she could remember, but had nothing done to relieve that condition. There were protrusions at every stool and some were out all the time. Severe bleeding accompanied every defecation. One week previously she noticed a swelling which became larger and more painful until about two days ago. After continuous application of heat, this swelling opened up in two or three places with a profuse discharge of pus and blood. She complained of severe and continuous pain, could not sit, stand, or walk without pain, and would not allow her bowels to move on account of the pain she anticipated. For the past three days she complained of difficulty in voiding, the pain being especially severe at the end of the act of micturition.

On examination I found a heavily built woman, weighing about 190 pounds, who had to be assisted on the table by two of her relatives. She was suffering from an ischiorectal abscess discharging a very foul smelling pus typical of a colon bacillus infection, from three fistulous openings—fissure, external and internal hemorrhoids, and a pedunculated polyp which got caught in the grasp of the sphincter muscle after each defecation. Her temperature was 104°, due to the infection.

I immediately had her admitted to the St. Mark's Hospital and ordered her prepared for operation the following morning. Her general condition and the state of her heart contraindicated the use of a general anesthetic, and her family physician advised against it, but he suggested the use of a local anesthetic. On account of the tissues being so much infiltrated with pus, I feared using a local anesthetic on account of the possibility of spreading the infection when using the needle for the injection of the local anesthetic. The operation, however, being imperative, I suggested the synergistic analgesia after the method of Dr. Gwathmey, but without the paraldehyde, and ordered three hypodermic injections of an eighth of a grain of morphine sulphate, in ten c. c. of a chemically pure solution of magnesium sulphate, twenty-five per cent., to be given at twenty-five minute intervals, the last injection to be given about twenty-five minutes before the operation. After the usual preoperative preparation and antiseptic precautions, the ischiorectal abscess was opened, the fistulous tracts laid open, the hemorrhoids were operated upon by the ligature operation, the pedunculated polyp was ligated and removed, and the sphincter muscle was incised to relieve the spasm produced by the fissure. The edges of the wound were then trimmed to prevent their turning in and to insure proper drainage of the very extensive wound, exactly as if the patient were under a general anesthetic. This was the only anesthetic used. The patient had no pain during the entire operation, was taken back to her bed and the following morning had a normal temperature. She was free from pain during and after the operation and did not require any postoperative morphine as is usual in other cases. She was discharged five days after the operation. Postoperative catheterization was not necessary in her case and she made an uneventful recovery, the wound healing entirely in a period of eight weeks. This case encouraged me in the use of synergistic analgesia in extreme cases where either local or general anesthesia is not feasible or is contraindicated.

Case II.—On December 26, 1921, Dr. M. Lubman referred to me Mr. S. R., aged forty-nine, a furrier by occupation, complaining of protrusions during defecation for the past twenty-five years, accompanied by blood and pain during as well as after stool, the protrusions requiring to be returned manually. The patient had been badly constipated for the past three weeks, but suffered no pain except during the time that the protrusions were outside, and this pain would be relieved when the protrusions were returned manually. He felt fairly comfortable about the rectum, outside of the discomfort and weakness following the passage of blood, until three days ago, when, after straining at stool, he noticed a huge mass protruding from the rectum, about the size of his fist, and which he could not return. This mass was hard and very painful and there was much continuous bleeding both from this mass and from the rectum. Examination revealed a very extensive mass of both external and internal thrombotic hemorrhoids, with areas of broken down tissue due to friction against the clothing and some gangrenous tissue due to the interference with the circulation of the parts. This man was much afraid of an anesthetic, so I decided to try again the synergistic analgesia as in the previous case. He was immediately sent into the St. Mark's Hospital, and was operated upon the following morning at 9 a. m., after having received three hypodermic injections each of one eighth grain of morphine sulphate in ten c. c. of a chemically pure solution of twenty-five per cent. magnesium sulphate, given at 7:45, 8:10, and at 8:35 a. m. I performed a complete hemorrhoidectomy, external and internal, using the ligature method, and although the patient was a bit frightened at what was going on, suffered no pain during or after the operation, did not require the usual postoperative dose of morphine, and had no interference with urination. He was out of bed the following day, and on the third day went home. He made an uneventful recovery.

Case III.—On December 17, 1921, Mr. J. F. called to see me with a history of having had an abscess about the anus seven years before, and was operated upon, being confined to bed for ten days. He had felt well until five months ago, when he noticed pain and swelling in the same region. He went to the same doctor who had sent him to the hospital for another operation, where he was laid up for two weeks, and one week later he required another operation on account of the formation of another abscess. Since then he had noticed a continuous flow of pus. Examination revealed a fistula with two tracts leading to an opening anteriorly between the external and internal sphincter. I advised operation, but the patient was so scared that he did not show up again until February 28, 1922, two and a half months later, during which time he had been under treatment by the same physician who had operated upon him previously. He then went to see Dr. L. Breinin, who referred him to me.

The patient told me that he had been laid up with a very bad case of influenza and bronchitis, and would not under any condition take any form of anesthesia. I decided to try again the synergistic analgesia. On March 1, 1922, after having received three injections each containing one eighth grain of morphine sulphate in ten c. c. of a chemically pure twenty-five per cent. magnesium sulphate solution, given at 8:45, 9:10, and at 9:35 a. m., he was operated upon at 10 o'clock. He was extremely nervous due to the fear of the previous operations he had undergone, but I laid the tracts open, dissected away all of the scar tissue, so as to encourage the formation of a flat, smooth scar rather than permit numerous hard linear scars, dissected away enough tissue to insure free and proper drainage, trimmed the edges of the wound, etc., the same as if he had been under a general anesthetic. He had no pain during or after operation, and left the hospital on the third day. He made an uneventful recovery.

Case IV.—On March 19, 1922, Mr. S. G. was referred to me by Dr. L. Bernstein. The patient, aged fifty-one, who had been working at umbrella handles, complained of blood and protrusions with every stool for the past twenty years. Those protrusions, he said, remained out for about half an hour to an hour before he could return them. He suffered from constipation and had been in the habit of taking cathartics for the past twenty years. He had been to a number of physicians, but refused any form of operation and obtained no relief. I sent him to the People's Hospital, where on March 21 he was given the injections as in the previous cases at 6:45, 7:10, and 7:35, and was to be operated upon at 8 a. m. He was so hypersensitive and so irritable that it was necessary to supplement the synergistic analgesia in his case with a local anesthetic, using one fifth per cent. of quinine and urea hydrochloride. A complete hemorrhoidectomy, ligature method, was performed, the patient evincing no signs of pain. He reacted differently from patients who are operated upon with the quinine and urea alone as a local anesthetic inasmuch as he did not require any postoperative dose of morphine.

Case V.—On March 23, 1922, Mr. S. B., furrier, aged forty-eight, came to me complaining of blood and protrusions with stool for the past eighteen or nineteen years. For the past three weeks he had felt worse than ever before, having noticed that the protrusions were out all the time, were much larger and more painful, but there was no blood. The pain was continuous, and more severe after stool. He purposely refrained from moving his bowels on account of the pain he anticipated. Examination revealed external and internal hemorrhoids, a fissure, and a blind internal fistula, due to an infection of the fissure. He had a typical furrier's chest, suffered from asthma and emphysema, and was a very poor risk for general anesthesia. On March 27, 1922, at St. Mark's Hospital, at 10 a. m., he was operated upon, after having received three successive injections of one eighth grain morphine in ten c. c. of a chemically pure solution of a twenty-five per cent. magnesium sulphate at 8:45, 9:10, and at 9:35 a. m. Although he was an exceedingly nervous patient, the sphincter muscle was cut to relieve the spasm for the fissure, the fistulous tract was opened, the edges trimmed for proper drainage, the external and internal hemorrhoids were removed by the ligature method, and a pedunculated polyp, which was not discovered at the time of the first examination, was ligated and removed. During and after the operation the patient did not complain of any pain and it was not necessary to give any postoperative sedative. The patient left the hospital after three days and made an uneventful recovery.

Case VI.—On March 20, 1922, Mr. A. D. was referred to me by Dr. J. Lempert. The patient was a printer, aged thirty-four years, and gave a history of having been operated upon at St. Bartholomew's and at the Polyclinic hospitals about thirteen years before for an abscess and fistula. He was laid up for a few days and had been feeling well after receiving treatments for a number of weeks, until four years ago when he noticed blood with every stool and also protrusions. He had been constipated for a very long time, and three days before he had a very large movement, since which time he had suffered from severe pain, especially after defecation.

Examination revealed ulcerated internal hemorrhoids and a fissure. I sent him to the St. Mark's Hospital where on the following day, at 2 p. m., after having received the injections as in the previous cases cited, at 12:45, 1:10, and 1:35 p. m., he was operated upon. But he was so extremely hypersensitive and nervous that it was impossible to even get near enough to him to find out whether any analgesia was produced, so it was necessary to supplement the synergism with nitrous oxide and oxygen to produce unconsciousness. The usual ligature operation for hemorrhoids and cutting of the sphincter for the fissure was performed and the patient suffered no postoperative pain requiring further sedatives, in spite of the fact that he was so hypersensitive.

CONCLUSIONS.

I do not wish to be misunderstood. I do not believe that synergistic analgesia can or ever will supersede general or local anesthesia for rectal operations, but in a few selected cases, such as those enumerated above, where a general anesthetic is contraindicated, or where, on account of an extensive suppurative process existing in or about the field for operation, endangering the spread of infection when a needle is used for producing local anesthesia, synergistic analgesia, as described, will frequently help the surgeon out of a dilemma. This may be supplemented with gas oxygen, if necessary, and will minimize the danger of a general anesthetic.

Advances in Röntgen Therapy with Special Reference to High Voltage Homogeneous Rays*

By WILLIAM H. DIEFFENBACH, M.D.,
New York,
Roentgenologist to Broad Street and Community Hospitals.

The subject of röntgen or x rays has been of great interest to me ever since their discovery and I have employed them clinically for over twenty-two years.

Since 1900, when various observers noted the action of the x rays upon the skin, with the production of dermatitis, alopecia and pigmentation, there have been waves of enthusiasm followed by depression as clinical results were confirmed or criticized and denied by members of the profession. With the usual conservatism of the profession, the general acceptance of x ray and radium therapy has been gradual but progressive, as results were demonstrated by the various pioneers.

When the limitations of röntgen and radium therapy are recognized, prognosis will be guarded in all but superficial malignancies and in circumscribed glandular lesions and skin diseases. It must be recognized that these vibrations in order to affect the tissues must permeate and penetrate them and the recent advances in deeply filtered x rays, producing radiations approximating the gamma rays of radium now furnish such an agency. With the three hundred thousand volt radiations we are still some distance from the million voltage of radium, but the goal may soon be reached. What we still lack in gamma rays quality we now have in augmented quantity and surface dispersion far superior to former doses.

It must always be borne in mind that these vibrations respond to Arndt's law and that small doses of x rays stimulate tissues and that deficient doses for inhibition of tissues are worse than useless. Inhibitive doses given with due regard to the condition of the patient and location of the lesion should always be applied in order to control malignant or benign growths. When a primary inhibitive dose cannot be applied at one sitting, the divided dose should be given within as close a period as the condition and reaction permits.

Attempts to achieve a dose destructive to cancer cells at one seance have been particularly cultivated in Germany where a number of clinical centres, Freiburg, Erfurt, Frankfurt, Breslau and Berlin, have announced specific doses for, respectively, carcinoma and sarcoma, the former at an increase of the erythema skin dose, the latter somewhat below it. The desire to achieve this "knockout" dose, while laudable, is fraught with much danger and cannot be accepted by those who have had years of experience with x ray therapy. The general adoption of this socalled cancer dose will be the cause of many deaths and tend to discredit röntgen therapy as a whole.

It must be remembered that it is the reaction of the sick individual to this powerful agent which determines the curative result and that age, complexion, nutrition and physical condition as a whole produces a variable result.

This powerful agency cannot be applied like a yardstick and the ionization measurement now recommended will fail as all other measurements failed as a standardization of dose. The human organism simply cannot be successfully controlled in this manner and many other elements besides the primary dose of x rays or radium radiations must be considered by the conscientious operator. An aged person, for instance, can stand a much larger skin dose than a child; a brunette more than a blonde; a negro or Chinaman more than a Caucasian.

---

*Read before the Bergen County Medical Society, January 13, 1923.

The blood picture must be carefully considered for a hyperemic patient reacts differently from an anemic one. A patient suffering from bacterial or tissue toxemia can in no respect react like an individual in fair health. To attempt, therefore, to prescribe a massive knockout dose for malignancy is bound to be hazardous and fail in many instances.

The location of radiation also calls for much discretion. To attack an inoperable cancer of the breast or lung situated on the left side with massive doses involves cardiac changes which may be disastrous. In treatments about the liver or kidneys the same warning must be emphasized. The effects of the rays upon pituitary, thyroid, parathyroid, adrenals and gonads with resulting hormone deficiencies must be borne in mind. In treatment of the uterus, cystic or intestinal changes must be anticipated. It must also be remembered that the action of the x or radium rays are not entirely local but that all workers agree that the secondary radiations produced in tissues constitute an active factor in therapeutics. Thus we have noted on several occasions when raying a breast lesion, with the abdomen covered with lead screens, that amenorrhea was induced.

Following the bombardment of the tissues with the rays, a tissue toxemia, the socalled *röntgen-kater* or röntgen malaise is noted. This toxemia requires a number of days for its dissipation and is associated with nausea, nervousness and mental irritability and diminution of the alkaline reserve in many instances. We combat these symptoms with indicated remedies and have had particular satisfaction in prescribing the alkaline Kalak water six ounces every four hours given well diluted, continued for a number of days.

Following the suggestion of a French surgeon, Dr. Dubard, of Dijon (1), we have for the past four years given magnesium compounds to combat the stated tissue salt deficiency found in malignancy. We prefer to give milk of magnesia two to four drams night and morning for this purpose.

The elements of the new röntgen ray therapy with the production of homogeneous rays of deep penetration, as we employ them, are as follows:

1. Voltage controlled by sphere gap. The maximum crest at three hundred thousand volts.
2. Milliampereage: This is controlled by a double meter and carefully watched by an attendant. In order to preserve the life of the especially constructed Coolidge tube, the milliampereage is kept at four ma. throughout the treatment.
3. Spark gap: Maximum gap twenty inches; we employ sixteen to eighteen inches.
4. Distance of target to tissues averages twenty to twenty-eight inches.
5. Filtration: For the past five years we have used one sixth mm. of metallic silver with secondary filter of wood. This filtration furnishes the most satisfactory homogeneous rays we have thus far tested.
6. Time: Unless contraindications are present the primary inhibitive dose is forty minutes over one portal. Two or three portals are used at one seance in certain deep seated lesions or when crossfiring is employed.
7. Ionization measurements have not been employed, as the exact value and reliability of this technic is *sub judice*.
8. Repetition of dose: This requires experienced judgment. As a rule we do not repeat the raying of any lesion under two weeks and prefer to wait three weeks, except in emergent conditions where the necessity of controlling the lesion promptly is so great that the danger of severe toxemia is accepted as less harmful than the delay in treatment. Transfusion can be kept in mind if the toxic reaction to the rays is too severe.
9. Area to be rayed: The area should be larger than the visible or palpable lesion—the larger the better—in order to prevent recurrences from nonaffected outlying malignant cells. Viscera not intended to be rayed should be covered with the heaviest lead protection. Adjacent and distant lymphatics should be rayed after the original focus has been treated.
10. Secondary rays: It is now fully accepted that secondary rays are produced in the tissues following röntgen ray treatments and that these in turn produce constitutional effects. This can be easily studied in the blood picture. A few hours after treatment leucocytosis with special increase in the polymorphoneutrophiles is noted, to be followed by leucopenia. The lymphocytes are particularly reduced, the x rays and secondary rays having selective action upon glandular structures. Anemia is noted and hemoglobin reduced. Workers in radium mines have in a number of instances developed marked blood and splenic diseases.

The necessity of furnishing foods and medicines rich in mineral constituents in view of the fact that tissue salt deficiencies are usually found associated with malignancy seems indicated. Bearing in mind the reactive toxemia and inhibitive effects upon all viscera, the same care and attention as are given in cases of febrile and infectious diseases must be given after all massive radiations.

I have observed anuria—temporary—in cases where radiation was directed near the kidneys and arrhythmia has been of frequent occurrence. Gastric disturbances have been a usual accompaniment but these are as a rule charged to tissue toxemia. In a recent case Addison's disease appeared to complicate a malignancy treated some distance from the adrenals. Eliminating from this discussion the large class of diseases of the skin, we will confine ourselves to partially listing the malignancies where röntgen therapy has proved of value and where the new technic is especially useful.

SUPERFICIAL EPITHELIOMA.

It has been found that the basal cell epithelioma responds to filtered radiation in nearly all cases. A word of caution: in order to obviate peripheral recurrences—ray double the surface of the visible lesion. The prickle cell fungating epithelioma is often refractory and requires heavy primary doses. Small doses are likely to stimulate these lesions.

SARCOMA.

Lymphosarcoma and round cell sarcoma, if they are sufficiently rayed, respond in a good proportion of cases. Metastasis, however, is so insidious that, unless outlying and distant lymphatics are included in the treatments, one sector may be apparently inhibited only to find recurrences in another. These lesions must be kept under constant supervision for a successful issue. Melanosarcoma and mixed cell sarcoma respond less frequently than the kinds mentioned above and but few instances of osteosarcoma or chondrosarcoma have been reported cured.

ADENOCARCINOMA.

Adenocarcinoma requires heavier doses than sarcoma and a crossfire treatment with massive raying is usually employed. Papillary carcinoma can be inhibited but colloid cancers are more resistant.

MEDIASTINUM AND LUNGS.

Mediastinal tumors and pulmonary cancer, while inhibited in some cases, still present a large mortality. Improved technic has recently shown better results than in former years.

LIVER, STOMACH, PANCREAS, SPLEEN.

In malignancies of the liver, stomach, pancreas and spleen radiation has thus far been of only temporary benefit. Heavy doses, unless confined to only a portion of the viscus at a time, are likely to hasten *exitus lethalis*.

KIDNEY.

Kidney malignancies offer the same difficulties as the larger viscera. Extirpation of a sarcoma or hypernephroma, if followed by postoperative radiation, may produce inhibition of the function of the remaining organ and extreme care must be exercised in the doses to prevent kidney insufficiency.

INTESTINE.

In intestinal malignancies, after resection, postoperative raying has been beneficial. Where operation was contraindicated, radiation has prolonged life. In rectal lesions the local application of radium following which the deep rays were applied have apparently inhibited the malignancies in cases not too far advanced.

PELVIC TUMORS.

In fibroid tumors of the uterus intrauterine applications of radium plus the x ray are disputing the field with surgical extirpation. In cases of hemophilia, cardiorenal or other constitutional surgical contraindications these new measures are absolutely justifiable. In cervical malignancy radium plus deep x ray radiations has replaced the scalpel in many European clinics.

Preoperative and postoperative radiation is indicated where surgery is to be invoked in uterine or ovarian malignancies. In the clinics at Freiburg, surgery has been practically abandoned in pelvic malignancies and deep, crossfire x ray treatments substituted.

BLADDER.

In cancer of the bladder radium and deep therapy are receiving extensive trial in many bladder malignancies. We reported the first case of inoperable bladder malignancy apparently inhibited for four years in 1910 with a dose of 2200 m. gr. hours of radium, the latter being introduced through the exploratory incision.

PROSTATE.

In cancer of the prostate gland there are a number of lesions on record where after shelling out the tumor and postoperative radiation there have been no recurrences. The application of deep therapy via perineum and the use of radium needles offers a favorable attack on these lesions.

PENIS.

Cancer of the penis has been treated with high voltage rays successfully. Careful protection of the testicles is essential. Radiation of inguinal glands should be concomitant.

CANCER OF THE VULVA.

If this lesion is of the prickle cell variety it is often very resistant and must receive heavy doses and inguinal gland treatment.

MEATUS.

Caruncles or epitheliomata of the meatus respond to radium radiation in practically every instance.

The theories as to the action of the deep x or radium rays upon tissues can be explained as follows:

1. In massive doses these rays are inhibitive and destructive to cellular life as has often been demonstrated by the examination of rayed tissues removed from the living.

2. If the doses are not excessive and are not repeated too soon, reparative sclerosis follows the cellular disintegration in the attacked region.

3. Constitutional: Following the tissue destruction, tissue toxemia supervenes and if this toxemia is not excessive, the organism through the well recognized principles of immunity and autotherapeutic mechanism establishes resistance to the malignant invasion which prevails for a long period. We consider it prudent to administer moderate doses of x rays at intervals of one month, even after all evidences of malignancy have disappeared, in order to keep up this constitutional resistance.

CONCLUSIONS.

The claim can now be made that by means of röntgen ray and radium therapy, the former over large the latter over circumscribed surfaces, we can now control or inhibit cancer cell proliferation. This can be demonstrated daily in private practice and in clinics in lesions not too far advanced, to those who have an open mind on the subject.

In advanced lesions the combination of surgical removal plus x ray, preoperatively and postoperatively, prolongs life and sometimes cures.

In hopeless, inoperable lesions, temporary relief of symptoms and prolongation of life can be assured and in isolated cases apparent cures are achieved.

Our armamentarium has certainly been strengthened by the addition of the deep therapy technic and in a few years new paths will be blazed in the fight against malignancy.

A Case Report of a Cyst of the Epiglottis Presenting Some Unusual Features

By H. MARSHALL TAYLOR, M.D.,
Jacksonville, Florida.

In reviewing the literature on cysts of the epiglottis, one cannot but be surprised at the relatively few references to this subject in the American textbooks on laryngology, many of the authors making no mention of it whatever.

A comprehensive survey of the literature shows that the Europeans have been by far the more prolific writers on this condition, as evidenced by the fact that of the forty-two case reports of cysts of the epiglottis which were reviewed, thirty-three of them were by European authors. In recent years it seems that few statistics have been collected, and we are forced to judge of its relative frequency by the collections of the earlier European writers. As early as 1877 Beschorner collected 693 cases of laryngeal growths, of which forty-five were cysts. Fourteen of these were located on the epiglottis. In 1881 Moure collected sixty-eight cases of cysts of the larynx, of which twenty-three were located on the epiglottis. He states that cysts of the epiglottis occur less frequently than intralaryngeal cysts and that they are generally on the lingual surface. Purseigle states that of all tumors of the epiglottis up to 1905, forty per cent. were cysts.

Chiari, in his chapter on cysts of the larynx, says: "They owe their origin very infrequently to the mucous glands. In addition they arise from distended blood or lymph vessels as well as from serous effusions into connective spaces. Mucous cysts develop from the glands through retention after the closing of their openings as the result of inflammatory, ulcerative or cicatricial processes. Through this retention of the secretion the acini or tubules become distended, their walls become stretched and gradually eroded, so that ultimately a round sack develops which is lined within by a cuboidal, or a flattened pavement epithelium. The cyst is covered without by mucous membrane, which is at first red, but later becomes pale and translucent as the pressure becomes greater. Almost always one sees upon the surface single or branching bloodvessels."

If the forty-two case reports which were reviewed could be taken as a criterion, it would seem that age has little influence on the occurrence of this condition. The ages ranged from the newborn up to sixty-five years. As to sex in the forty-two case reports, these growths were found more frequently in the male than in the female in the proportion of two to one.

As to the location of the cyst in this review, they were found more frequently on the lingual surface of the epiglottis then on the laryngeal surface in the proportion of six to one.

The case herewith reported seems of particular interest on account of one condition. After a careful search in the literature I have been unable to find the description of a similar one.

Case.—The patient, L. H., male, aged twenty-seven, farmer, weight 118. His father died of tuberculosis at the age of sixty. The patient consulted me on January 10, 1921. The only complaint elicited by the patient was a description of severe, distressing choking sensations extending over a period of seventeen months. To quote him briefly, he stated that on August 10, 1919, he was suddenly awakened with a choking sensation. He felt that someone had their hands on his throat. On assuming an upright position the sensation subsided. On finding no one in his room he concluded he was dreaming. This experience was forgotten until a week later when he was again awakened by this same choking sensation. That night he was awakened three times by what he described as attacks. From that time until the date I saw him, these choking spells reappeared frequently and lasted longer, only occurring while in the reclining position or at times when taking violent exercise. He asserted that he never had any cyanosis, for by forcibly expiring or a slight cough the sensation would be overcome temporarily. There was no impairment of voice or difficulty in swallowing.

On my first examination, by depressing the tongue the cyst was easily seen. Laryngoscopic examination showed a round tumor one and a half cm. in diameter involving the lingual surface and right lateral border of the epiglottis, crowding the epiglottis posteriorly and to the left. The tumor was glistening and of grayish color, with a smooth surface traversed by several large bloodvessels. To the probe it was soft, elastic and insensitive to the touch. A diagnosis of a cyst of the epiglottis was made and operation advised. The patient refused operation and was lost sight of for approximately one year. On January 24, 1922, he again called on me in desperation, saying that he could stand his condition no longer. He stated that his choking spells had become so severe that he was afraid to go to sleep. On falling asleep he would wake up screaming and clutching at his throat, often finding himself at an open window gasping for air.

By direct examination the tumor was again observed, and the upper and right lateral border of the epiglottis could be seen to be markedly depressed posteriorly. On January 25, 1922, at St. Luke's Hospital, I suspended the patient. The tumor was grasped with fixation forceps and with curved scissors excised at its base. There was an immediate discharge of a yellow gelatinous fluid. The point of attachment was then cauterized.

Dr. A. C. Broders, of the Mayo Clinic, made the following report: The examination of the specimen of the epiglottis shows it to be a true cyst, or perhaps a better term would be cyst adenoma. While it is lined to some extent with squamous epithelium, there is also a good deal of columnar epithelium which undoubtedly secreted its contents. The rest of its wall is fibrous tissue with some inflammation.

Much to the disappointment of my patient, without speaking of my own chagrin, at the end of seven weeks there was no change or abatement in the severity or frequency of these severe spells of choking. Another direct laryngoscopy was made. There was no recurrence of the tumor and the closest examination failed to reveal its former attachment. However, the epiglottis was still turned on itself and occupied the same plane that it did prior to the removal of the cyst. In the reclining position the epiglottis could be seen to tilt further backwards and on forced inspiration was drawn downward toward the larynx. I could only account for this phenomenon on the theory that the prolonged pressure of the cyst had interfered with the resiliency of the epiglottis, which seemed to be more flabby and resembled somewhat the infantile type of epiglottis.

The picture of this atypical epiglottis combined with a group of symptoms in some respects resembling laryngeal stridor recalled to my mind the case report of Dr. Samuel Iglauer of an epiglottidectomy for the relief of laryngeal stridor.

On March 21, 1922, seven weeks after the removal of the cyst, during which time the patient was having these nocturnal attacks of choking, the epiglottis was exposed by the direct laryngoscope, and that portion showing a definite entropion was removed by the use of the alligator punch forceps. The amount of hemorrhage was trivial. The patient for five days following complained of some pain on deglutition, but otherwise was not inconvenienced.

Seven weeks after this procedure the patient states that he has not had any tendency toward his former paroxysms. His rest at night is unbroken and, furthermore, violent physical exertion can be taken without any inconvenience to his respiration.[1]

Some Clinical Manifestations of the Anaphylactic Reaction*

By JOHN F. ANDERSON, M.D.,

New Brunswick, N. J.

I have chosen as the subject of my paper a discussion of some of the clinical manifestations of the anaphylactic reaction. At first this may seem to be largely a subject of theoretical interest and of but slight practical application; but such is not the case for some of the anaphylactic reactions have recently been shown to be of the greatest interest to the clinician. Before entering upon a discussion of some of the clinical forms of anaphylaxis, it would be well to review briefly the experimental basis of anaphylaxis and its development.

Anaphylaxis, also called hypersusceptibility, supersensitiveness, or allergy, is a condition of unusual or exaggerated susceptibility of the organism to foreign substances. The word anaphylaxis was introduced by Richet to describe a condition contrary to prophylaxis. As we now regard the phenomenon, the word is a misnomer, for we look upon the condition of hypersusceptibility as an important phase of certain kinds of immunity. In fact, protection against a large class of infections depends upon an altered power of reactions, i. e., hypersusceptibility or anaphylaxis.

This state may be congenital or acquired, and is specific in nature. The condition of anaphylaxis may be brought about by the introduction of any foreign protein into the body. Hypersusceptibility to proteins that are nonpoisonous in themselves may readily be induced in certain animals.

An animal may be in a condition of hypersusceptibility and immunity at the same time. The two conditions are closely interwoven; the latter is often dependent upon the former. Von Pirquet advises that the term immunity be limited to indicate the condition of complete resistance in which no clinical reaction occurs when poisons such as diphtheria, tetanus, and similar materials are introduced into the organism. He suggests the term allergy to indicate conditions of acquired immunity associated with anaphylaxis.

Allergy, then, as the word indicates, is an altered power of the organism to react. When this power of reaction is increased, we say that the body is hypersensitive or in a state of anaphylaxis.

It has long been known that the blood of certain animals is poisonous when transfused or injected into certain other species. But the blood serum of the horse apparently lacks such poisonous action. Large quantities of the blood serum of the horse may be injected into man, rabbits, guineapigs, and many other animals without serious inconvenience except occasionally a slight reaction at the site of inoculation.

It has been shown that ordinarily horse serum is a comparatively bland and harmless substance when injected into certain animals; but these animals may be rendered so susceptible that an injection of horse serum may produce death or severe symptoms. For example, large quantities of horse serum may be injected subcutaneously into the peritoneal cavity, into the brain, or directly into the circulation of a guineapig without apparently causing the animal the least inconvenience. If, however, a guineapig is injected with a small quantity, say 0.0004 c. c. of horse serum, and, after the expiration of a certain interval, again injected with horse serum, the result will probably be fatal. The first injection of horse serum has sensitized the animal in such a way as to render it very susceptible to a second injection of horse serum. The same phenomenon may be induced by the use of any other protein.

A certain time must elapse between the first and the second injection before the animal becomes susceptible to a second injection. This period of incubation is from seven to twelve days, and corresponds suggestively with the period of incubation of the serum disease which von Pirquet and Schick placed at eight to thirteen days.

---

*Delivered before the Middlesex County, New Jersey Medical Society.

Guineapigs may be sensitized with exceedingly small quantities of horse serum. In much of the work quantities less than 0.004 c. c. were used, and it was found in one instance that 0.000,001 c. c. of horse serum was sufficient to render a guineapig susceptible to a second injection, and guineapigs may be sensitized with 0.000,000,05 of a gram of egg albumen freed from the other proteins of egg white.

It also requires very small quantities of horse serum when given in a second injection, to produce poisonous symptoms. One tenth of a cubic centimetre injected into the peritoneal cavity is sometimes sufficient to cause death; 0.1 c. c. subcutaneously may cause symptoms, while much smaller amounts given into the brain or directly into the circulation may be fatal.

The subject of anaphylaxis has been a fruitful subject of research in many laboratories for the past few years and an understanding of the experimental results has resulted in clearing up many previously not well understood clinical conditions. The most important manifestations of anaphylaxis from a clinical viewpoint are:

1. Serum sickness or the train of symptoms that may follow the injection of serum or antitoxin.
2. Idiosyncrasy to proteins, or as it is commonly spoken of—allergy.
3. The immune reaction to smallpox vaccine.
4. The tuberculin reaction.

SERUM SICKNESS.

All who have administered therapeutic serum have experienced occasionally a train of symptoms coming on after a period of from one to thirteen days following the injection, depending chiefly upon whether the person has previously received an injection of serum. As a rule, the symptoms following the injection of the serum have been mild and without danger, though sufficiently frequent and troublesome to call for much study and attempts to discover methods of prevention. A few cases are on record in which sudden death has followed a single injection of serum; but there are no reports in the literature, so far as I am aware, of fatalities following a second injection, although not infrequently such cases have shown alarming symptoms. A matter of much interest is the comparison between symptoms occurring in subjects after the first injection of serum and those following repeated injections. It has been shown that the symptoms following the second injection were not only more severe than those following the first, but developed after a very much shorter latent period.

In the first injection cases the symptoms usually appear in from eight to twelve days, while, after the second injection, this incubation period may be considerably shortened and the symptoms appear in from three to seven days—the local and general reaction being very much more marked than those following the first injection. This quickened reaction or response of the individual has been termed by von Pirquet and Schick the accelerated reaction and differs from the symptoms following the first injection only in occurring more quickly and being more severe. The second injection cases may show a train of symptoms sometimes coming on less than twenty-four hours after injection and characterized by marked local erythema and edema, sometimes by urticaria and constitutional disturbances.

The percentage of instances and variety of symptoms vary according to the reports of different observers. A rash of some form occurs in from seventy to eighty per cent. of all cases showing a reaction, joint pains occasionally accompanying the appearance of the rash and not infrequently there is an enlargement of the lymph glands, particularly those in the neighborhood of the injection. Albuminuria is common and fever usually present. Perhaps the symptoms of which the patient complains most bitterly are those attendant upon the rash, which produces a feeling of tightness of the skin, with marked pruritus, and on account of the involvement of the mucous membranes, particularly of the upper respiratory tract, there may be in some cases difficulty in breathing. Occasionally, on account of the involvement of the intestinal tract, there is diarrhea.

A matter of much practical importance in connection with serum sickness arises in connection with the administration of prophylactic doses of antitoxin. I am often asked whether it would be safe to give a patient who has previously received a dose of antitoxin another injection some months or years afterwards, and my reply has invariably been that while in my opinion it is probably safe as concerns the life of the individual, the patient and the family should be warned that the second injection is likely to be followed by a train of symptoms described as serum sickness. It is important to know that the injection of any kind of serum in persons who are subject to asthmatic attacks may be followed by alarming symptoms and even death. This class of persons in some way have become acutely sensitive to the protein of horse serum. These reactions to the serum protein are not the same as in serum sickness, but probably should be included under the type of cases discussed in the next heading. When the injection of horse serum, normal or antitoxic, is indicated in asthmatics, the physician should be careful to inform the patient or family of the possible serious aftereffects.

Another matter of importance is the prevention or treatment of the symptoms of serum sickness. It has been suggested by European workers that it would be advisable in the case of persons who have previously received an injection of serum to administer one tenth c. c. of serum followed an hour or two hours later by the full therapeutic dose, and this method has been used quite extensively in connection with the administration of antipneumococcic serum. For the treatment of the condition, after it has once developed, there is no real specific but relief of some of the symptoms may be had by the administration of adrenalin chloride, by sedatives, and by the use of bicarbonate of soda baths. The bowels of the patient should be kept freely open, and the patient kept on a liquid diet.

ALLERGY, POLLINOSIS OR PROTEIN SENSITIZATION.

When Anderson and Rosenau of the Hygienic Laboratory, in 1908, in their Harvey lecture, first suggested that some cases of idiosyncrasy to food might be due to a sensitization of the patient to those food products acquired in an unknown manner, and that this phenomenon might be regarded as a manifestation of anaphylaxis, it was thought that like true anaphylaxis, allergy was of such rare occurrence as to class it as a medical curiosity. It was so regarded until Schloss confirmed the sensitiveness of a patient to egg protein by means of the skin reaction and later succeeded in desensitizing him by repeated injections of pure egg protein. The origin of such sensitization in many cases is still unknown, but for purposes of study, they may be divided into two groups: inherited and acquired, the greater number falling into the first group.

Allergy which, in the beginning, was regarded as largely of theoretical interest, by reason of the large amount of study of the past few years, is now definitely established as an important factor in a variety of clinical conditions. Skin tests with allergens or pure proteins have been of the greatest assistance in the diagnosis and subsequent care of many cases of asthma, hay fever, and vasomotor disturbances of the upper air passages, eczema and other skin affections, angioneurotic edema and disturbances of the gastrointestinal tract. Many of the sufferers from these conditions give a positive skin test to more than one allergen or protein and consequently should be desensitized to each positively reacting protein.

Sensitiveness to proteins from food substances, epidermal products, pollens and bacteria may be readily demonstrated by the intradermal test or the cutaneous test with the preference, especially on account of its absolute safety, to the latter.

The test is simple and easily done. A satisfactory method is to bare the forearm and wash the inner surface where application is to be made. Use sterile water or physiological salt solution only. (Do not use alcohol, ether, or similar substances, which interfere with the delicacy of the reaction.)

Make a single scarification, not more than one eighth inch long, with a sterile needle or use an instrument such as the von Pirquet borer. Penetrate the outer layers of the skin only, care being taken not to draw the blood. Rub into the tissue at this spot the soluble protein, either in the form of the dry powder with a drop of sterile decinormal sodium hydrate or bicarbonate or as a ten per cent. dilution in sterile physiological saline or sodium bicarbonate solution. A series of scarifications and inoculations may be made at the same time.

When desired, a one twentieth to one per cent. solution of the allergen may be prepared, and injected intradermally with a tuberculin syringe and fine needle in doses of one hundredth to two hundredths cubic centimetre each. This is strictly an intracutaneous inoculation and must not be confused with a subcutaneous injection which, in cases of hypersensitiveness, is sometimes hazardous.

When either technic is employed, controls with the salt or alkali solution alone must be made by the same method for comparison.

If hypersensitiveness to a given protein exists, there will appear about the site of inoculation a distinct urticarial wheal, having a sharply defined but irregular border, within five minutes to half an hour, and often lasting for several hours.

After the diagnosis has been made of the offending protein specific treatment may be started in the endeavor to desensitize or render immune the patient to the offending protein or pollens. In food sensitization the omission of the food found as a cause or strongly suspected by reason of a positive skin reaction in many cases relieves the patient of his symptoms, although in some cases on account of the importance of the article in the dietary, it may not be possible to omit it from the diet.

In such cases and where there is sensitization due to pollens, bacteria or epidermal substances, the desensitization by subcutaneous injection should be attempted. The strength of the injections should always be controlled by the results of skin tests of the strength of solution to be injected. For example, if the patient gives a positive skin reaction to a one to 5,000 dilution, the first injection should be from a solution not stronger than one to 10,000.

The treatment in cases of pollinosis should be begun sufficiently in advance of the seasonal appearance of the offending pollen to have the patient in condition to resist the effect of the pollen.

If we vaccinate a person with potent vaccine virus who has never before been vaccinated, we obtain a reaction which begins on the third or fourth day by the formation of a papule which goes through the various stages of vesicle, pustule, and the final formation of a scab which, when removed, leaves the typical scar of a successful vaccination against smallpox.

This entire reaction occupies approximately three weeks. If, however, the individual has previously been successfully vaccinated or has had smallpox, the reaction will be accelerated in development, shortened in time, and decreased in severity. The papule will appear earlier, the vesicle will be smaller, the area will be less intensive, and the entire reaction may be complete any time between the fourth and eighth day. If the immunity of the individual is very high, acceleration of the reaction may be so great that it consists only of the papule and areola, reaching full development in twelve to sixty hours after vaccination. This accelerated reaction may be taken as evidence of immunity and is a true anaphylactic reaction.

It is of practical importance in demonstrating whether the individual who has previously been vaccinated still retains his immunity.

When tuberculin is injected into a normal individual in not excessive amounts no reaction follows the administration. If, however, tuberculin be injected into an individual suffering from tuberculosis, except in the very late stages of the disease, there is a response on the part of the individual to the products of the tubercle bacillus, as shown by the local reaction, fever, and increased activity of the tuberculous process. This reaction can be obtained in varying degree by the subcutaneous injection of the tuberculin, by intradermal administration, by means of inunctions containing tuberculin, or by instillation into the eye. They all indicate an increased susceptibility or state of anaphylaxis on the part of the individual to the products of the growth of the tubercle bacillus. They are important for diagnostic purposes and perhaps for the treatment of certain forms of tuberculosis, particularly localized and chronic types.

The Dawn of Surgery: Its Armamentarium

By JONATHAN WRIGHT, M.D.,
Pleasantville, N. Y.

The volume or volumes that might be written on the surgery of man would contain much to astonish those historians of medicine acquainted only with the timid attempts to relieve sufferings by surgery at the dawn of the historical period, and it would still further interest the modern surgeon by bringing to his notice, as hoary with antiquity, ideas of the technic of his art usually conceived to be of recent date. It would require a volume of no mean size to set forth this matter which really lies behind the low state of surgery we find in Hippocrates and even in Celsus, for we have no reason to suppose that what primitive men in a primitive environment do now was essentially different from what they did during the existence of the older civilizations. Making due allowance for the filtering of civilized arts through ever wilder zones of culture to those most remote from the modern or ancient centres, primitive surgery cannot have differed much at any time from that which existed when no centres of civilization can be said to have begun. Civilized tribes and arts may have retrogressed at all periods and what we see may sometimes really hail back not to the dawn of surgery but may have descended from the zenith of some forgotten civilization or from some lost offshoot of one with which we are familiar. If this is to be kept in mind it may also be well to remember that specific arts may have withered and become blighted in a civilization from special and exceptional causes, while even great advance has been registered in other fields. Such I believe was the case with surgery before Hippocrates. Unwise legislation, as I have before remarked, was evidently at the root of this, supported by religious intolerance encouraging a wizard "to whine a song over a sore that craved the knife."

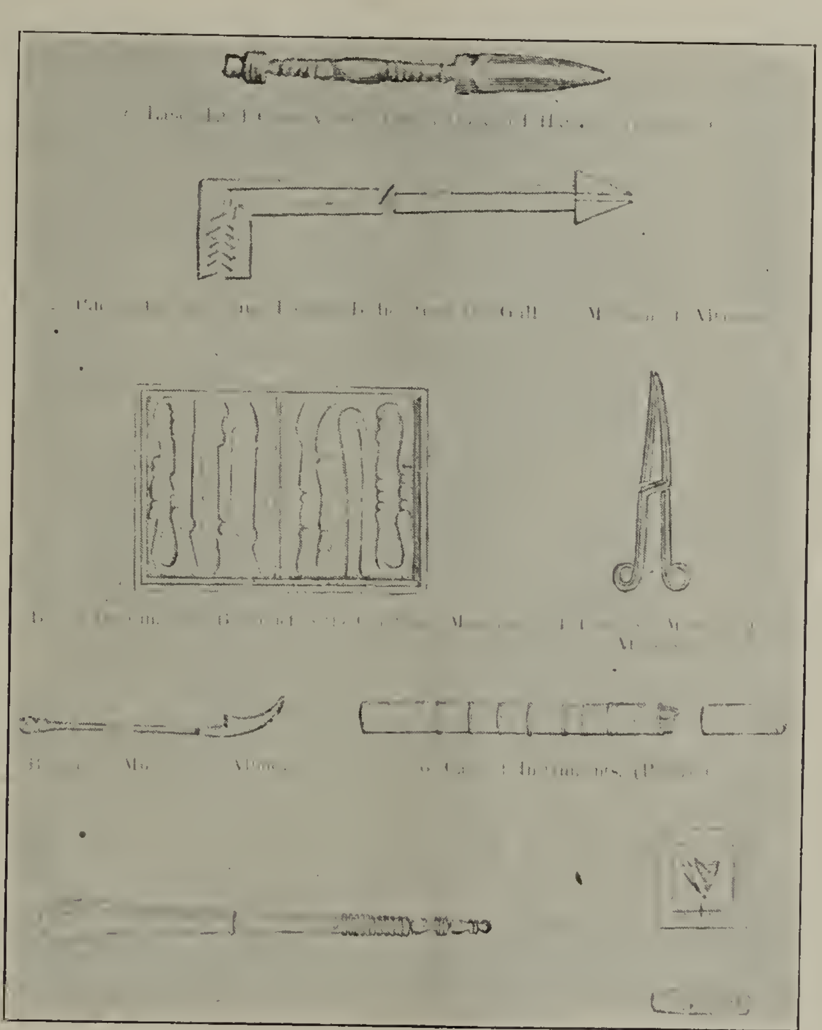

Fig. 1. Ancient Roman instruments from various places.

Where I have brought this into prominence we were busy with the splints and reduction apparatus of Hippocrates for dislocations and fractures (1), which more recent writers have pictured to themselves he must have used. As to the latter, modern surgery like primitive surgery gets along better without such formidable and complicated contrivance, but in Africa the Baganda (2) "fitted sticks along the broken bone after removing the flesh from it and bringing it into position; the splint was fitted along the bone and left there and the flesh was brought back to cover it. The wood used for this purpose was from the strychnine plant." Among the Melanesians (3) "they have an excellent method of treating a fracture of the tibia. They take about two and a half inches of the green sappy stalk of the tagete (Cordyline terminalis) and insert it about one and a half inches in the medullary canal in the upper part of the bone. They then violently extend the limb, bringing the orifice in the lower part of the bone opposite the projecting end of the stick"—in short, they make a dowel joint utilizing the medullary canals of the long bones. I will not stop to inquire what the results were. The Polynesians, however, as another observer (4) remarks, use splinters of bamboo cane, much as we did a few years ago, and are expert in the treatment of dislocations, the author reporting also, in all the innocence found in the Hippocratic Corpus and its commentators until within a century or so ago, what he supposed was a successful technic in reducing dislocations of the neck. Dobrizhoffer (5), too, in the eighteenth century, found Paraguayans skillful in the treatment of fractures. De Sahagun also saw the ancient Aztecs (6) reducing fractures and dislocations when the Spaniards arrived. The Sinaugolo (7) of British New Guinea pad with leaves the splints they bind on with long strips of the dried cortex of the banana. The Naga tribes of India (8) and the pagan races of Borneo (9) as well know the use of splints, and the Afghan doctors, it is said (10), use a plaster of the yolk (white?) of egg and flour, the germ of the plaster splint. Even among the Shoshone in America (11) they knew, before the white men taught them, how to splint a fracture with willow twigs. A more thorough perusal of the records of modern primitive man, of which this is but a glimpse of the fractures and dislocations, soon establishes a conviction that even in this field, where Hippocrates himself has written so much and so well, there must have been a retrogression from the practices of primitive men, for we see them making use of the armamentarium which Nature has furnished them with a skill and a boldness and a freshness of thought not to be found even in the best books of the Hippocratic Corpus. They, too, were chary of amputations, not because of established law, but because in fractures especially they as a rule believed in conservative surgery.

We should expect them skilled in the extraction of foreign bodies and they were. The extraction of arrow heads was probably the first difficult job the army surgeon of primitive man encountered. No other has more exercised the ingenuity of his descendants. The barbed head, even when the shaft remained attached, made it a problem and a very painful one. In New Guinea, the sloping spines of the arrow head severed from the shaft baffled a native operator under the observation of a modern witness (12). After tugging at it "he succeeded in getting a string around it, and bending over the top of a strong sapling he tied the other end of the string to that, and then releasing the tree it sprang up with great force. The patient let forth a yell of agony, but the arrow head was dangling at the end of the string. The wound left behind was a frightful one, but in the space of a short time the patient entirely recovered, although the arrow head had been deeply embedded in the shoulder and chest." When a leg or arm has a spear embedded in it the Samoans (13) push it through. Among the Fijis (14), more than a hundred years ago with a sharp piece of bamboo crossed incisions were made over an arrow head sticking in the chest of a native and carried down to the bony walls, the noose of a string was passed over the barbs and the head was pulled out with some of the lung substance clinging to it. A dressing of banana leaves and cocoanut oil was prepared. A pledget of it was rolled up and kept in the bottom of the wound, renewed with the dressing from time to time. Convalescence was prolonged for a twelve month, but the banana leaves and the oil and bamboo splinter and the seton worked all modern surgery could, on the average, expect and vastly more than modern surgery, before antisepsis, dared hope in such a case with vastly more evolved surgical supplies.

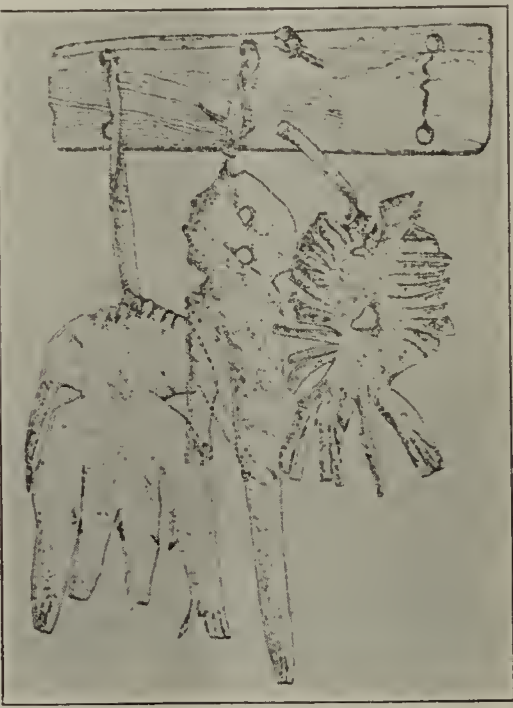

FIG. 2.—Shaman's ivory knife; length: twenty-seven cm.

In Uganda (15) they pierce the chest wall for pleurisy "until air escapes through it (sic). In a few days they appear to be quite well and simply dress the wound with butter." Sir Harry Johnston needs now no support for his statements, but as to cases where pleurisy among savages is treated successfully by paracentesis and the collapse of the lung, one may as well mention that Hobley (16) tells the same story for East Uganda. We are familiar with the stories of the recovery of the wild man from frightful injuries and desperate illnesses under surgical and medical treatment, but we see the suggestion in the sequence in which I have placed the above accounts that observation of wounds of the chest may have led the savage surgeon to advanced modern surgical treatment for medical disease.

With the subject of craniotomy there are connotations which are of the greatest interest outside strictly surgical lines. When a prehistoric man had a headache he concluded apparently, and from his point of view the conclusion was entirely logical, that a devil was inside his skull and that the proper thing to do was to have a hole made in it and let him out. There is much more to the story of the large number of skulls found in various parts of the world, exhibiting two or three or more perforations, often evidently the result of repeated operations. Peru has furnished a number of these skulls to many of the museums in many other cities both in this country and in foreign lands, but a great collection of them may be seen in New York in the American Museum of Natural History. Broca (17) and Lucas-Championnière (18) and the French have had opportunities of studying the operation in modern times among the Kabyles, one of the hill tribes of northern Africa, who practice it still. In prehistoric times it was apparently so widespread a practice as to take its place as a manifestation of an essential part, the demonology, of primitive thought. The transmission from demon etiology to the splendid word neuralgia is a natural one perhaps, but its connotation of thought with intracranial pressure is manifest. In the Loyalty Islands at Uvea it is said (19) the operation still prevails for neuralgia, dizziness and other cerebral affections. The ancients in the time of Hippocrates took no such chances of curing such things. Often, in tropical lands, a cocoanut shell is used as a prothesis to cover the hole in the skull. They also trephine the long bones for rheumatism. Among Polynesian savages (3), too, one finds them occasionally raising depressed bone in fractures of the skull, using as a knife and scraper a sharpened sea shell. Ninety per cent. of recoveries are claimed by one wondering observer from the lands of asepsis and the modern surgical supply companies.

Innumerable accidents by flood and field made primitive man fertile of resources and he sought in the nature about him an armamentarium ready made to his hand and he frequently found it so, but his ingenuity was also diligently set at work by the accidents of savage life. Various forms of the ritual of magic called for mutilations of the parts which partook of the nature of surgery or opened the door to it. The amputation of finger joints comes down to us from the cave man (20). We shall have to speak of circumcision as well as the surgery of parturition. Front teeth were not only broken off, but filed and filled and noses and lips pierced to enhance the beauty of women and the dignity of man and they all had their varying technic and the simple instruments with which to accomplish it.

We naturally know more about the instruments of prehistoric man than we do the purposes to which they were put, but many if not all of their uses have been revealed by the study of modern primitive men. In the stone age Lubbock (21) mentions many implements with which current literature has now made us more or less familiar. Some of these we have every reason to believe from what we know of modern primitive man were devoted to surgical purposes. From the above we have just had a hint that palaeology can have revealed only a modicum of the resources at his command In the Terramara settlements among the ancient Lake dwellers of Central Europe, but also elsewhere, notably among the Esquimaux in modern times, very delicate and minute tools have been preserved (22) which testify to his manual skill and this doubtless was exerted as well on the anatomy of man as upon the many objects of which daily use was made for utility or adornment. The kitchen middens ransacked by research in many parts of the world have emphasized the resourcefulness of early man. The wonderful flint knives from Egypt, to be seen in the New York Metropolitan Museum, are testimonials to the efficiency of the cutting edges of primitive tools. Some egyptologist, I remember, but whose record I will not try to find in my notes, in comparatively recent times has said that he once knew an old Egyptian fellah who habitually used a flint knife to shave with, not so handsome doubtless as those of six thousand years ago which lie in the museum cases, but efficient in his hands though perhaps somewhat painful. Yet it is in Egypt also we get the first glimpse of iron.

Nevertheless it was with iron that the Pelasgai from beyond the Black Sea, it is thought, carved their way even into Egypt around the Mediterranean land routes, bronze and iron swords in their hands and metal armor gear on their backs, which Elliott Smith (23) thinks the Egyptians gave to the world in the first place. Some go so far as to say (24) that not only was copper known eight thousand years B. C., but bronze manufactured as early as 4800 B. C. did not come into general use until three thousand years later, and iron was known four thousand years before its economic use. The stone age, palaeolithic and neolithic, the bronze age, the age of iron, are about as indefinite, vague and unscientific ways of dating time as could possibly be invented, on that account probably so extremely useful to palaeologists and so popular with their interpreters. They overlap one another to such a degree that one is safe in referring almost anything to any one of them. The old gentleman shaving with a flint knife in modern Egypt is an epitome of the criticism of this terminology. If the working of iron first began in Africa, as Schweinfurth (25) thinks, we may well imagine as we look at the stone images and temples of ancient Egypt in their ruins that there is found its first use in the arts of civilization. Sidereal iron and probably copper was known to much more primitive men, but was worshipped, not used, by them when they first began to invent, even in the earliest stone age, but when iron was first given a hard cutting edge, then only did it begin to count for civilization. That is the event it is hard to date and the rest of the chronology in the story of iron does not assume much significance in the history of ancient civilizations for surgery or any other of man's arts. It is, however, the subject of endless discussion by archeologists. As to this point and as to the similar one of glass they have cast history adrift.

Much more frequently than as a shaving implement do we find flint still in use for ritual purposes in sacrifice or in circumcision in modern times. This reverence for its efficiency pursued religion into the surgery of the medicine man. The shaman's knife was so used long after the white man brought the Indian something better for his surgery as well as for his warfare, but in America, for the latter at least, he had already begun to use the copper, but copper alone never anywhere ever completely displaced the stone cutting implement. Even bronze displaced it only partially, but when iron began to take an edge, I know not exactly when, then ended the first dawn of surgery and its approach to the zenith, as we with imperturbable vanity call our own epoch, began.

Health Conditions in the New York City Prisons

By JAMES A. HAMILTON, Ph.D.,
Albany, N. Y.,
Secretary of State

Sanitation, personal hygiene, and general health, play an important rôle in the study, care and rehabilitation of the delinquent. A healthy mind goes hand in hand with a healthy body, and a physically normal inmate is more receptive to our correctional program than one who is lacking in bodily vigor or who is handicapped by disease or abnormalities.

The personnel consists of resident doctors and nurses supervised by John M. O'Connor, M. D., medical director, who is responsible to the Commissioner of Correction through a medical board composed of leading members in the different specialties of their profession, who outline the general policy. Harmonious cooperation between the medical bureau and the executive offices has been an important factor in producing the excellent results in the medical department.

SANITATION.

Eternal vigilance on the part of the sanitary officer in each of the department's institutions has enabled us to prevent epidemics of diseases, particularly insect and vermin borne. The old jail fever, which at times carried off the major part of the prison population, is heard of no more. Old buildings, formerly the source of disease and the nidus of pestilential epidemics, are clean and healthy. Daily rounds are made by the resident physician (the chief sanitary officer) who makes a careful inspection as to the quality and quantity of the food, its wholesomeness and its preparation.

Cleanliness of the inmates' cells, bedding and wearing apparel, is enforced. Personal cleanliness and good habits of the inmates are insisted upon. The recommendations of the chief sanitary officer to the warden take precedence over all orders. In addition visits are made from time to time by sanitary officers of the Department of Health. Vermin exterminators visit each institution and a general cleaning and sterilization of blankets and bedclothes is constantly conducted.

PERSONAL HYGIENE.

On arrival, inmates are compelled to take a shower before presenting themselves for medical examination and they must bathe thereafter at least once a week. There are resident dentists at each of the two general hospitals and visiting dentists for the outlying institutions that are not in direct contact with the island hospitals. Each inmate receives a thorough dental examination and whatever work of a temporary nature that is necessary is performed. Permanent mechanical dentistry is available for all those who desire it. Inmates have their own barber shop where all the sanitary laws of the Department of Health are complied with. Toilet articles and tooth brushes are available for all.

GENERAL HEALTH.

The department maintains on Welfare (Blackwell's) Island two general hospitals, one for men and one for women, with branches at both Riker's and Hart's Islands.

On admission, inmates are divested of their clothing and are taken before the doctor for a searching preliminary examination. They are then assigned to the quarantine quarters, unusual cases being referred to the visiting and consulting staff pending final disposition. After a brief quarantine, inmates are assigned to their respective wards, or, if apparently normal, are immediately sent to the custodial prisons for classification and study by the executive officer of the respective clearing houses.

HOSPITAL WARDS.

The venereal wards for male patients are located at the penitentiary, Welfare (Blackwell's) Island, where venereal diseases occurring in the male receive treatment. To these wards are sent incoming inmates when found to be diseased.

The latest methods of treatment are used for gonorrhea. This service is being equipped to take care of all phases of the work, including the surgery of the sequelæ and complications.

GONORRHEA IN THE FEMALE.

Women convicted of prostitution are examined by medical officers of the Department of Health for evidence of venereal disease. Those found diseased are divided into two classes and disposed of as follows: a. The youthful, who are taken to Kingston Avenue Hospital, Brooklyn, for treatment by the Board of Health. b. The older, or more hardened offender, is sentenced to the Department of Correction Hospital (Workhouse for Women), Welfare (Blackwell's) Island.

Due to the fact that it is often difficult, even in a flagrant clinical case of gonorrhea, to demonstrate the gonococcus in the vaginal or cervical discharge, laboratory findings in gonorrheal cases are disregarded. All prostitutes, then, sent to the Department of Correction are required to take treatment for gonorrhea for a minimum of thirty days. The average number of women under treatment for gonorrhea daily is 104, out of a total census of 330. While forty per cent. of the women convicted for all crimes need treatment for gonorrhea, but five per cent. approximately of the men have acute symptoms. Gonorrhea does not always produce pain and discomfort in the female and is resistant to treatment. Women often go through their daily duties, innocent of the fact that they have gonorrhea. Prostitutes may cohabit, ignorant of their having this disease. On the other hand, the male must needs take treatment to relieve a painful affection.

In 1920 the treatment for syphilis and gonorrhea was outlined in detail by a board made up of consulting physicians of the Departments of Health and Correction.

Essentially the treatment of syphilis consists of the administration of salvarsan and mercury over certain periods of time. It has been exceptionally successful in reclaiming a great many individuals who not only would have been lost to the State, but also would have served as the foci or infection for the spread of these very loathsome diseases. Two hundred and eleven females received treatment for syphilis. Five hundred and eight males were also treated for syphilis.

DRUG ADDICTION.

Riker's Island is the hospital for the treatment of drug addiction in males. Our wide experience in the handling of drug addicts and our painstaking study of these individuals have developed a welldefined and definite policy for their care. This plan hinges on our conception of the medical and economic status of a drug addict. All students of drug addiction are grouped into two schools: First, those who believe drug addiction a disease; and those who believe with us that it merely is a pernicious habit.

Custodial care is necessary, and the treatment must be undertaken in institutions who have real custodial powers. It is useless to consider the treatment of drug addiction unless you have complete control and supervision of the patient and it is best that they be treated in correctional institutions.

Riker's Island, therefore, is essentially a hospital. Custodial officers are present to enforce order and discipline and to carry out the policy of the treatment that is dictated by the medical board in cooperation with the warden. In 1921 the Municipal Farm, Riker's Island, received and treated 2,197 drug addicts.

TUBERCULOSIS.

All male tuberculous cases are sent to Hart's Island to the tuberculous hospital there. The female cases are retained at the Correction Hospital on Welfare Island. One hundred and ninety-five male tuberculous cases were admitted during the past year. Of these 105 were complicated by drug addiction. Only four out of the 195 died, which is a remarkable showing, especially when we consider that we care for tuberculosis patients in all stages and also when we realize the high percentage of tuberculous cases that must receive treatment for drug addiction before we can start restorative measures to counteract the lung conditions. One hundred and forty-five cases were discharged improved, the average gain in weight being fifteen pounds. In addition to the tuberculous ward at Hart's Island there are excellent wards for the treatment of general medical cases, and also minor surgery.

SURGERY.

It is in this department that our results have been really spectacular. All surgical cases, both male and female, have had a very happy result. The women especially have been given through surgery the opportunity to keep away from the use of narcotic drugs. By far the great majority of the female drug addicts that come to us have some pelvic pathological condition that might be a cause for their continuing the use of morphine or heroin. Those who have signified their willingness have been operated upon and we have been successful in every case. There have been no surgical deaths and no infections.

The following operations, among others, have been performed:

Hernia	61
Circumcisions	21
Mastoids	4
Appendix	12
Inguinal adenitis	4
Hydrocele	6
Epididymectomy	5
Phimosis	2
Tonsillectomy	17
Varicocele	5
Orchitis	4
Gastronenterostomy	2
Decompression for depressed fracture	1
Cholecystectomy	4
Hysterectomy	5
Salpingectomy	19
Suspension of uterus	2
Uterine polyp Bartholin glands excision	2

GENERAL MEDICINE.

The following are some of the more serious cases that have received attention in our hospital:

Alcoholism	32
Acute myocarditis	6
Pleurisy	4
Otitis media, acute	2
Peritonitis	2
Obstipation (from drug addiction)	2
Cystitis	6
Pyorrhea adnexal disease acute	10
Herpes zoster	2
Influenza	140
Bronchitis	14
Uterine hemorrhage	2
Pregnancy	5
Arthritis deformans	4
Miscarriage	1
Nephritis, acute	3

NEW HAMPTON FARMS.

Owing to its distance from the city, the reformatory at New Hampton maintains its own general hospital. How successfully it is operating is attested by the history of the following case:

On February 18, 1921, inmate known as R-7173 was transferred to the Reformatory and was received in a semiconscious state. He was immediately sent to the hospital. Upon arrival the resident physician found that the inmate already lapsed into unconsciousness. A diagnosis of sporadic cerebrospinal meningitis was made. Two other physicians were consulted and a lumbar puncture made, which confirmed the diagnosis. This inmate remained unconscious for three days. On the third day his speech returned but was not coherent. He was given nine injections of antimeningococcus serum and kept on improving until April 26th, when he was given a special invalid parole. The resident physician has since seen this inmate. He is normal in every way, showing no paralysis or any of the other sequelæ to this disease.

PSYCHIATRY.

Sixty-one patients were committed to Matteawan as insane misdemeanants. One was transferred to Dannamora as an insane felon. Seventeen patients were sent to the State Institution for Mental Defectives at Napanoch.

The data that we have received from mental examinations have determined us to develop further psychiatric investigations and to recommend a thorough mental examination whenever feasible before trial.

Editorial Articles

THE QUESTION OF BLOOD TRANSFUSION

Although blood transfusion has been practiced for almost three hundred years, it was only placed on a really scientific basis a few years ago. It is gratifying to national pride to know that during the past thirty years most of the contributors to the science of transfusion have come from this country. At the beginning of the present century Crile worked out in great detail direct transfusion, but this method was superseded by the exigencies of war conditions. It is worthy of notice that blood transfusion is one of the valuable medical and surgical procedures improved out of all knowledge during the war, and also one of the few thus improved applicable to civil practice. It is obvious that blood transfusion is called for frequently in the time of peace.

At a meeting of the Medical Society of London, held on November 27 last, a discussion was held on blood transfusion in civil practice. Mr. Geoffrey Keynes, who opened the discussion, pointed out that there were now two transfusion schools, first, those who held that plain whole blood should be used, and second, those who believed that blood containing an anticoagulant was efficient. He further pointed out that while the whole blood method was satisfactory in the hands of those who were accustomed to it, it was the use of an anticoagulant which popularized transfusion and made it a certain and easy process.

Among the indications for blood transfusions the first and greatest was severe hemorrhage and shock. Gastric ulcer, especially in young patients, was another type of case suitable for transfusion. Another group of cases was the preoperative cases, and the speaker emphasized the point that many cases which were a serious operative risk on account of previous debility, as in carcinoma, were rendered an ordinary risk by prior transfusion. Mr. Keyes then discussed postoperative transfusion, and went on to say that, generally speaking, the use of transfusion in Great Britain was restricted. It had made much greater strides in America.

The most difficult matter to decide was when transfusion should be done, and Dr. Alexander Fleming referred to the work done in the war by Bruce Robertson, of Canada, and Brock, on the volume of the blood in bad cases of hemorrhage in which the anemia was very severe. The total hemoglobin in the blood in these cases was seriously reduced. A good indication of this loss was derived from the blood pressure readings. When the hemoglobin was reduced below a certain stage, regeneration of the blood from the marrow did not take place, but if a transfusion was given and the hemoglobin content raised, the marrow again functioned. There is no doubt that blood transfusion in selected cases is a very valuable procedure, and may and does not infrequently save life. Of course, it has not been perfected as yet, but it has been greatly improved by reason of the lessons of the war, and in the future will be more used in civil practice than it is now.

CANCER IN DOMESTIC ANIMALS

There is no subject in pathology more interesting or deceiving than that of cancer, and the enormous amount of research work carried out by highly competent observers during the past twenty years has not advanced the solution of the problem to any marked extent. Each time that a conscientious observer exposes the results of his work, the clearest conclusion that one comes to, invariably, seems to be the objection that he puts forward to the results of his predecessors. The latest and most important contribution to the study of cancer, that due to Cadiot, does not escape this criticism.

It is common scientific knowledge that cancer in animals is identical with the same pathological process in man in its nature, localization and evolution. The first consideration is not denied by Cadiot, but on the other hand he mentions many peculiarities relating to the latter two. As to evolution, it is to be remarked that the gravity of neoplasms appears to be less in animals, as the process may last for many years—even cancer of the kidney—without giving rise to cachexia. On the other hand, malignant growths are unquestionably less common in animals than in man, and in spite of what has been said in this respect, there may be a relative immunity in some species which compensates for a greater sensibility to the process in others. Carnivorous and herbivorous animals are equally prone to manifest cancer.

It cannot be denied that the localization of cancer is a question of race. In dogs, cutaneous cancer is the most frequent, while it is rare in other animals. Cancer of the penis and præpuce is more often met with in the gelding than in oxen, and is never seen in stallions and bulls. Cats and bitches are subject to cancer of the breast, while other female animals are usually free from it.

If cancer of the digestive tract is considered comparison with the human species becomes particularly instructive. For example, there are three authentic cases of cancer of the esophagus in horses, and this neoplasm is, according to really conscientious statistics, twenty-five times less common in animals than in man. Gastric cancer, rare in all animals, is nevertheless met with in the horse with relative frequency, but is forty times rarer than in man. On the other hand, gastric cancer develops in dogs one hundred times less than in man.

Cancer of the rectum, tongue and lips is absolutely exceptional in animals, while uterine cancer is more particularly met with in cows, and is infinitely rare in carnivorous animals, proportionately about sixty times less often in the bitch than in woman.

These figures are much more demonstrative when they give the proportion between the animal species than when they aim at a comparison with human beings. In point of fact, cancer increases in animals—as in man—with advancing age, and the question arises as to what may be called the cancer age in animals? It is certain that many of them are killed before reaching it, either for meat or for other reasons, and Cadiot has taken this fact into consideration when discussing the frequency of cancer in the herbivorous and carnivorous. This would seem necessary to bear constantly in mind, and that it is susceptible of causing a certain general reserve when establishing comparisons between animals and man.

On the other hand, it is difficult not to accept Cadiot's conclusion that the nature of the animal's food has no influence over the greater or lesser frequency of malignant processes in them. The carnivorous, especially, are not especially exposed, and even the amount of flesh they consume certainly has no importance in this respect.

Cadiot maintains that irritation, be it digestive or external, does not explain the genesis of malignant growths in animals, and the proofs put forward by him are unquestionably convincing, but he refers to numerous irritating agents to explain the frequency of cancer of the penis in geldings, such as putrefied smegma and dust rich in bacteria.

It might be remarked that some biologists maintain that if irritative states apparently predispose to cancer the disease develops more frequently at points where this irritation—be it acute or chronic—has produced cicatrices which, on account of absence of blood supply and natural organic defense, appear to constitute the elective places for neoplastic development. And, although the data adduced by Cadiot seem to oppose to a certain extent the parasite theory of malignancy, neither do they agree with the many other explanations proposed for the genesis of these neoplasms. Especially can they not be invoked in favor of the dysembryoplastic theory, and in point of fact, why should there rather be a defective development of the tissues during embryonal life of the horse which later will be castrated, than in a horse that will remain a stallion?

It would seem more logical to publish data and endeavor to offer a positive explanation than to resort to negative ones in order to bring up objections to former theories, a condition of affairs that certainly obtains far too commonly among present day observers.

A SOCIAL SERVICE WARD AT ST. MARK'S HOSPITAL

Hospitals without bed facilities for venereal diseases are not doing their full public duty. Family manifestations of acquired and inherited syphilis are perhaps the most serious of the social disasters due to venereal diseases. Economically, anything less than the best and most intensive and persistent specific treatment places heavy burdens on the individual and later on the community. Whether we think of childless marriages, or of surgical emergencies and disabilities of women, the damages due to the gonococcus are serious alike to society and the infected person. Whether we deal with declared or unrecognized stages of either syphilis or gonorrhea, the expressions of both are so manifold that no hospital service lacks instances of them, whatever the specialty particularly served and whether children or women or men are accepted for care. It may well be considered that each case of venereal disease is the potential cause of an outbreak of the disease in the household or family, not always promptly, but quite likely to occur in the course of years or generations.

Social service has come to mean so much of human care and thoughtfulness that one balks at having the term applied to a ward used exclusively for venereal disease cases and suspects, as if venereal disease completely filled the content of the term medical social service. Would not the term family service ward be sufficiently distinctive and less of a plagiarism? But, by whatever name it may be called, its function is surely destined to be increasingly appreciated.

A ward such as that described in Dr. Pedersen's article, which appears on page 345, devoted to the sympathetic management and the scientific as well as social treatment of the lives blighted or threatened by venereal diseases, would be a boon to every hospital and dispensary, and contribute largely to the prevention of diseases of many kinds, mental and cardiac especially.

The spirit of the undertaking at St. Mark's Hospital and the policies formulated in regard to the relations between patients, their private physicians, and the families concerned, are admirable and may well serve as standards for similar wards which will doubtless be established with increasing frequency in the future.

As a resource of unusual value to the private physician; as a refuge for people across whose lives the disabilities of venereal disease have come by accident or abuse; as an assistance to the officer of health, the visiting nurse, the probation officer, the relief worker, this ward, combining as it does medical, diagnostic, and treatment service and social inquiry guidance and relief for this particularly urgent group of patients, will prove a boon of rare merit.

THE PREVENTION OF PHTHISIS AMONG PRINTERS

Dust and especially minute irritating kinds of dust excite into activity latent phthisis. Workers in trades in which dust is always present suffer greatly from respiratory affections and pulmonary tuberculosis in particular, and in proportion as the dust is small hard and irritating steel filings, so is the disease more prevalent. Dr. E. Halford Ross has been writing recently in the *London Times* on printers' phthisis and to enunciate the fact that silica-grit when breathed is the active factor in the causation of consumption. It is further maintained, and in keeping with this assertion, that the elimination of dust by constant cleanliness would bring about the prevention of this, the most prevalent disease among printers.

These letters gave rise to prolific and suggestive discussions. Dr. Ross has written in the *London Times*, January 26th last, relating the result of a practical test in this direction which he has made. The experiment was tried in the printing department of the Bank of England where, of course, phthisis had occurred. When the large building of the bank was nearing completion, some two years ago, it was suggested by the head of the printing department that a vacuum cleaning plant, with pipes carried to every floor, having a central exhaust engine with dust containers in the basement, might be a satisfactory means for keeping the new premises thoroughly clean. This was installed and has been used continually by a specially trained staff. Detailed medical notes and reports, from varying and independent sources, have been kept of all cases of sickness.

In order to make the experiment free from error similar records were also kept at another new factory near London which was engaged on similar work, but in which such cleaners had not been instituted. In neither of the works was there a picked population, but persons of all ages, including many newcomers, were employed. Two years of careful observation are therefore available. During the first year the new factory just referred to had five fresh cases, one of which has since proved fatal. It was then extracleaned and during the second year there were no cases of phthisis. But, and this is the point, the printing premises of the Bank of England, in the heart of London, have remained free from fresh disease throughout the two years. As Dr. Ross says, a remarkable result in a large staff engaged in a most phthisical trade.

The foregoing account affords a striking object lesson on the possibilities of preventive medicine. It is patent that if phthisis can be prevented in the printing trade, it can be prevented by similar or appropriate measures in several other trades. Dust not only excites to activity phthisis, but is a factor in the causation of many diseases and minor ailments and is the carrier of some hurtful germs, of how many we are ignorant. The elimination of dust in factories would be a long step on the road to a hygienic and sanitary ideal.

Good health is the most important individual possession and good health in the majority of a population of a country ensures national prosperity.

DEFICIENCIES OF DIET

It seems to be becoming more clearly understood by those who have made a special study of the subject that in diet rests chiefly the bodily salvation of the race, perhaps also to some extent the mental. Of course in considering this question many points must be taken into account. Climate is one aspect of the matter that is too often disregarded or its importance underestimated. In short, to a considerable extent, the kind and quantity of food taken must be adapted to the climate. In a tropical climate less protein, especially in the form of meat, is required, while in a very cold climate meat and fat must be eaten in large amounts in order to maintain the heat of the body.

But neither a very hot nor a very cold climate is conducive to the most vigorous health, or, at any rate, to long life, mainly for the reason that in a temperate clime a mixed diet can be easily procured and if taken in well balanced quantities is well assimilated and leads to good health and longevity. Further, the manner of life led must be taken into consideration and temperament and personal idiosyncrasies must not be neglected.

A great deal has been written and spoken recently as to what constitutes a wellbalanced diet, and in spite of numerous and painstaking investigations conclusions arrived at vary greatly. Within the past few years, in fact, since the discovery of those elements of the diet termed by Funk vitamines were discovered, their supreme importance has been constantly emphasized. At the present time, however, views in this direction have been somewhat revised, and the transcendental importance of vitamines is doubted. Most of the experiments undertaken to test the value of these elements have been made with rats, guineapigs, puppies, pigeons and so on, and are only partially comparable to human conditions. Some amazingly interesting practical experiments as to the significance of the presence of vitamines in the rations of farm stock have been carried on for some time at the Rowett Institute, near Aberdeen, Scotland. In the first report made for 1922, experiments are described which appear to show that it is more essential to seek for and supplement deficiencies in mineral constituents than to be oversolicitous concerning vitamines.

The conclusions based on farm stock, that is, civilized stock, bear a certain relationship to civilized man, so far as diet is concerned, and if these conclusions are confirmed will have a wide bearing. Broadly speaking, the results of experiments on young pigs showed that a vitamine deficiency had not so adverse an effect on health as a mineral deficiency. The addition of codliver oil had a definitely beneficial effect on health and rate of growth, but the effect was greatest when the diet was ill balanced or defective in its mineral constituents. It was found, moreover, that the beneficial effect of codliver oil was much greater in the case of sheep than of pigs.

Further studies were pursued dealing with the deficiency of minerals on young pigs, which deficiency produced a condition closely resembling that of rickets in children. On a ration consisting only of grains which contain an excess of magnesium, potassium and phosphorus and deficiency of calcium and sodium, a condition undistinguishable from that of rickets in children, both in symptoms and pathological effects, quickly arose. When codliver oil was given the general health of the animals improved and the onset of the symptoms was delayed, but the disease was not prevented. However, adjustment of the mineral contents of the ration enabled the animals to grow from the time of weaning to that of sexual maturity without any signs of rickets. In pigs, at any rate, the main factor in the production of rickets is the lack of the proper amount and balance of the mineral matter of the food. The beneficial effect of fat soluble vitamine A and sunlight is most marked where the mineral balance is defective.

The results of these experiments are very suggestive and tend to confirm the views of those authorities on diet who hold that a well balanced diet rather than one with its full quota of vitamine content makes for good health. Also they appear to demonstrate that a deficiency of the mineral salts is of greater consequence than a deficiency of the vitamine elements. Further experiments along this line will be followed with close attention as undoubtedly much of value is to be learned by researches on animals fed under civilized conditions.

THE DRUG HABIT

In Great Britain, at the present time, there is much discussion with regard to the increasing prevalence of the drug habit. Medical men are by no means exempt from criticism. It was reported in the lay press, according to a correspondent in the *Medical Press and Circular*, January 17th last, that an "eminent nerve specialist" had stated at a meeting of the Society for the Study of Inebriety, that out of every four British medical practitioners one was a habitual drug taker. As a matter of fact the speaker did not state of his own knowledge or experience that the sweeping indictment was true, but related it on the authority of Dr. Oscar Jennings in his book *The Morphia Habit and Its Voluntary Renunciation*, "that one medical man out of four is a drug habitué, usually a morphinist." It is to be hoped that this is an utter exaggeration, and there is no doubt that such is the case, but it is evidence of the increased prevalence of drug taking, or, at least, of the trend of public opinion.

As said before, in the lay press of Great Britain recently, the correspondence has been ample and profuse as to the widespread illegitimate use of harmful drugs, that is, harmful when not employed by medical men for the relief of pain, to induce sleep and so on. There is a suspicion amounting, in fact, to a certainty that certain drugs are used largely for purposes not legitimate. As Sir William Collins, a well known British physician, pointed out in the *London Times*, January 18, 1923, that in a report laid before the Assembly of the League of Nations in September last, it was justly observed that as long as dangerous drugs were produced in quantities exceeding the legitimate requirements, a great danger existed that the surplus would find its way into illegitimate channels. A control of production so as to limit it to the amount required for medical and legitimate purposes will, therefore, be the most effective way to put a stop to the illicit traffic.

This view was indorsed by the Assembly of the League. Sir William Collins, however, further pointed out that it had not been found easy to determine with accuracy and agreement what the legitimate requirements of these drugs were, 1, for the world's consumption, and, 2, to meet the demands of each particular nation. At the first Hague Conference in 1911, he made a small contribution to such knowledge by ascertaining that, at a particular London hospital treating some 138,000 patients annually, the consumption of opium in one year was less than thirteen pounds, and of morphine less than five ounces.

Recently it was ascertained that at ten large London hospitals, which treated more than seventy thousand inpatients and more than 550,000 outpatients in the year 1921, the amount of opium used in that year was less than forty-two pounds, of morphine less than five and a half pounds, and of cocaine a little over nine pounds. The writer went on to say that these relatively modest amounts of drugs included in the opium convention, which sufficed for the medical treatment of sick and injured persons, would tend to confirm the view that, of the hundreds of thousands of kilograms of opium raised, and of the tons of morphine manufactured and exported annually, there must be a large margin available for purposes which could only be described as illegitimate and pernicious.

With respect to cocaine, which is said to be largely used in Great Britain for purposes otherwise than medical, there appears to be no very valid reasons for its manufacture at all. The problem is international and can only be effectually solved by international action. If the abuse of drugs, which means drug addiction by a large number of persons, is to be prevented or even seriously checked, world wide drug control is essential. The question in this country, or rather perhaps in this State, has been for some time a vexed one. While it is allowed on all sides that the abuse of drugs is degrading and in a high degree injurious, it is also well understood that restrictions must not be enforced which will hamper the legitimate use of any drug by medical men. It appears that limiting the output of drugs such as opium, morphine, cocaine and heroine to legitimate requirements, or to as nearly an approach to these requirements as can be ascertained, is a sensible way out of the difficulty. It might not be amiss to pursue investigations as to legitimate requirements in New York and elsewhere in America.

ANNALS OF MEDICAL HISTORY

The Fall issue of the *Annals of Medical History* is a number of unusual interest. One of the principal and most timely features is the material on Pasteur. The cover bears the reproduction of one of the best known portraits of the great French scientist, and the frontispiece reproduces the famous picture of him at work in his laboratory. The leading editorial is an excellent résumé of his contributions to science and human welfare, and the book review section discusses his life by Descour. Among the special articles are the second instalment of Dr. Francis R. Packard's series, Guy Patin and the Medical Profession in Paris in the Seventeenth Century; Dr. George Dock writes on Robert Talbor, Madame de Sévigné, and the Introduction of Cinchona: an Episode Illustrating the Influence of Women in Medicine; Dr. Burton Chance discusses Some English Worthies of Interest to Ophthalmologists; Dr. Edward B. Krumbhaar contributes a very interesting article on the Early History of Anatomy in the United States; and Dr. Isador Coriat writes on Medical Magic and the taboos and primitive methods of treatment that have arisen from the conception of the physician as the possessor of supernatural powers. An editorial reproduces a page from the famous Edwin Smith Papyrus, an Egyptian manuscript written in the seventeenth century B. C., now in possession of the New York Historical Society, and gives an analysis of its contents. This document describes forty-eight cases, grouped in sections according to their anatomical classification. In addition to the valuable material contained within its covers, *Annals of Medical History* is of interest also because of the beautiful workmanship displayed. Rarely does a scientific work undertake to appeal also to the esthetic sense. The *Annals* is a triumph of the printer's art in illustrations, typographical work, paper, and general makeup.

◆

News Items.

German Congress for Internal Medicine.—The German Congress for Internal Medicine will be held from April 9 to 12, at Vienna, in the large reception hall of the Hofburg. The program for the Congress has already been arranged.

Bronx Pediatric Society.—The Bronx Pediatric Society meeting, on March 14, will be held at Daubert's, northeast corner Fordham road and Concourse. Dr. Lester J. Unger and Dr. Harry R. Litchfield will read the scientific papers of the evening.

Annual State Conference.—June 26, 27, and 28 have been selected by Dr. Hermann M. Biggs, State Commissioner of Health, as the dates for the Annual State Conference of Health Officers and Public Health Nurses. The Conference will be held at the Grand Union Hotel, Saratoga Springs.

Columbia Lecture Course.—The University Extension and the College of Physicians and Surgeons of Columbia University announce that registration for the course in Internal Medicine to be given by the staff of the Presbyterian Hospital, under the direction of Dr. Dana W. Atchley, will close June 1.

E. G. Janeway Lecture.—Under the auspices of the Mount Sinai Hospital, the E. G. Janeway lecture will be given by Professor J. J. MacLeod, of Toronto University, March 26, at 8:30 p. m., at the Blumenthal Auditorium, 1 East Ninety-ninth street, New York City, on "Experimental Work on Diabetes and Insulin." Physicians and their friends are cordially invited to attend the lecture.

Ninth Harvey Lecture.—The Harvey Society announces that John Howland, Professor of Pediatrics of Johns Hopkins University, will deliver the ninth lecture of the series on "Rickets" at the New York Academy of Medicine on Saturday evening, March 31, at 8:30.

The tenth lecture will be given on April 14 by Professor Otto Meyerhof, University of Kiel, Germany, on "Auto-Oxydation Processes in the Cell."

Civil Service Announcement.—The United States Civil Service Commission announces opportunities for appointment to persons who are qualified and who desire to enter the Government service at the new United States Veterans' Bureau Hospital for Colored Veterans, shortly to be opened at Tuskegee, Alabama, and erected on ground donated for the purpose by Tuskegee Normal and Industrial Institute.

Death Rate Increases.—The Department of Commerce announces that provisional figures compiled by the Bureau of the Census for the first nine months of 1922 indicate slightly higher death rates than for the corresponding nine months of 1921. For the States compared the death rate for the nine months was 11.7 in 1922, against 11.6 for the first nine months of 1921. The highest mortality rate for the nine months is shown for Maine (14.3), and the lowest for Idaho (7.8).

Fund for Pediatrics.—The College of Physicians and Surgeons of Columbia University has received from William Perry Watson, consulting medical director of the Prudential Insurance Company of America, a gift of $5,000 for the establishment of a permanent fund to be known as the Dr. William Perry Watson Foundation in Pediatrics. The annual income of this fund will be given in cash to the member of the graduating class showing the most valuable work in the study of the diseases of infants and children during a regular course at the college.

Scientific X Ray Heroes Win Carnegie Prizes.—The Carnegie Gold Medal was awarded to Professor Bergonie, of Bordeaux University. Professor Bergonie is a recent victim of x ray research, whose right arm and three fingers of the left hand were amputated.

Dr. Charles Vaillant, of La Riboisiere Hospital, who a short time ago underwent his thirteenth operation of amputation made necessary by the withering effects of x ray, and Professor Leray, another sufferer from the rays, will receive money grants from the Carnegie Foundation.

Site for New Hospital.—A syndicate of individuals interested in the work of St. Mark's Hospital has purchased the three five story tenements covering a plot seventy-five by one hundred in East Eleventh Street, opposite the Church of St. Mark's. The properties purchased by the syndicate are to be held in their present shape as an investment until St. Mark's Hospital can raise the necessary funds to erect a new building on this property for hospital purposes. Plans have been prepared but no improvement can be undertaken until the necessary funds, amounting to about $500,000, can be raised.

Fight Vivisection Bills.—Several physicians, including Dr. Simon L. Flexner, director of the Rockefeller Institute, declared at a hearing in the Senate chamber that the Coltillo-Leininger anti-vivisection bills were an unwarranted reflection on the medical profession in New York State. They asserted that it was ridiculous to think that unlawful experiments were ever made by doctors on children. Dr. William H. Parks, director of the laboratories of the Department of Health of the City of New York, declared experiments made by doctors in past years had greatly decreased diphtheria deaths in New York.

Grip and Pneumonia Gain.—The number of cases of sleeping sickness in New York have decreased, according to reports to the Board of Health, but there was an increase in pneumonia and influenza cases, due to the unfavorable weather conditions. The death rate for the week ending March 10th was lower than the week previous.

Typhus Plague in Russia.—Typhus as a great epidemic in Russia has passed, according to reports from Samara and Odessa received by the American Relief Administration. These cities are typical of their particular area, and though the reports are probably incomplete, they nevertheless give evidence of a great diminution in the disease. At Samara sixty-eight cases of typhus were reported in February and only one in March. At Odessa 2,506 cases were reported in February and only seven in March.

Academy of Medicine Needs.—The Academy of Medicine announced that it would try in the next few months to raise $250,000 from its Fellows and their friends to carry out the Academy's part of an arrangement with the Rockefeller Foundation and the Carnegie Corporation to construct and equip the $1,000,000 Academy Building, at Park avenue and Sixtieth street.

Both the Rockefeller Foundation and the Carnegie Corporation have agreed to contribute funds for the library and other educational utilities. One-quarter of a million dollars is needed to complete the purchase and to provide adequately for the operation of the new building.

Bequest for Fight Against Tuberculosis.—Announcement was made a few days ago, when the will of the late Dr. Karl Von Ruck, tuberculosis specialist, who died in Asheville, N. C., on November 5th last, was offered for probate, that he had bequeathed approximately $700,000 for scientific research into the prevention and cure of tuberculosis. The Von Ruck Research Laboratory, Incorporated, was created several years ago by Dr. Von Ruck, and will act as administrators of the fund, the earnings of which are to be expended "by the corporation or trustees for scientific research, study and experiment in tuberculosis and for the aid of tubercular patients who are unable to procure adequate and satisfactory treatment."

Hospital to Help Disabled Workers.—The appointment of Dr. Joseph A. Blake as surgeon in chief of the Reconstruction Hospital, 100th Street and Central Park West, is coincident with the decision of the trustees to proceed with extensive plans for the development of the hospital. The plans, including a new wing, to cost $1,500,000, already under construction, contemplate its development into one of the finest postoperative institutions in the United States. Electrotherapy, mechanotherapy, hydrotherapy and other methods of treatment especially designed to restore the functions of victims of industrial accidents or occupational diseases have been worked out with a remarkable degree of success at the Reconstruction Hospital. Even greater progress in the development and application of new methods of treatment are expected under the leadership of Dr. Blake, who worked out new methods of treating fractures used widely by the Allies during the World War. Dr. Charlton Wallace recently resigned as surgeon in charge of the Reconstruction Hospital.

Book Reviews

INTERNAL MEDICINE

Technik der wichtigsten Eingriffe in der Behandlung innerer Krankheiten. Ein Leitfaden für Studierende und Arzte. Von Dr. H. Stursberg, Bonn. Zweite, vermehrte und überarbeitete Auflage. Mit 49 Abbildungen im Text. Bonn: A. Marcus & E. Weber's Verlag, 1923. Pp. xii-176.

This is the second revised edition of a brochure dealing with the most important procedure in the treatment of internal diseases. Its publication was prompted by the author's experience in his association with students and young practitioners and also in his lectures on therapeutic technic and the practical procedures used. Most of the good larger works on the subject are not suitable for the student and the physician who has occasion to apply these procedures only rarely and who must acquire the technical details quickly in order to remember them; such books, furthermore, give a wealth of information, compelling the reader to select what he prefers, or they omit the necessary details entirely. This little book deals only with certain selected procedures that are simple, but sufficient and generally applicable. It goes into the most minute detail of every procedure mentioned, such as aspiration and injections, the local treatment of the esophagus and stomach, intestinal irrigations and injections and the use of the catheter and the local treatment of the bladder.

POSTOPERATIVE THERAPY

Therapeutique Postoperatoire. Par W. Rochard. Paris: Gaston Doin, 1922. Pp. 689.

This is a very well written and compiled book of about seven hundred pages. Its scope is quite broad, as it is intended for surgeons, general practitioners, and nurses. The first part of the book is taken up with general postoperative therapy, the various postoperative complications being discussed, while the latter part takes up the surgery of the various systems. In a consideration of the treatment following the various types of operations, the authors first discuss the normal postoperative therapy for each type of operation and then give in detail the treatment for practically all the postoperative calamities that might occur. This, of necessity, means that there is a good deal of repetition, but it is a great convenience if one desires to look up any specific type of operation.

There is a delightful thoroughness to the book and a decided effort shown to make the patient as comfortable as possible. In many places there is a distinct variance in therapy to our American ideas. For instance, in the treatment of shock, they advocate the use of stimulants such as camphor and caffeine and other drugs but no great emphasis is laid on the use of morphine. It is evident that the technic of transfusions has been more specialized in this country, for in their discussion of transfusions the authors give practically only two methods: first, the citrate method, and secondly, direct sutures of vessels. Very little mention is made or importance attached to either the syringe method, as popularized by Linderman, or the cannular method of Unger and Bernheim.

The reviewer is rather astonished to see no mention made of the treatment of high jejunostomy as a relief for paralytic ileus, an operation which has proved a real life saver in many cases if used early. The authors suggest cecostomy, but this has proved to be much inferior to high jejunostomy. Certain methods of treatment that they suggest are little used in this country. For instance, they advocate the injection of electrargol and gold colloidal solutions for the treatment of septicemia.

On the whole, the reviewer thoroughly recommends this book. It is written in a delightful style and is valuable for reference if one encounters some unusual postoperative complications.

NATURE OF NEGROID BODIES

Uber die Entstehung der Negrischen Körperchen. Von Dr. Ladislaus Benedek and Dr. Franz Oskar Porsche. Abhandlungen aus der Neurologie Psychiatrie, Psychologie und ihren Grenzgebieten. No. 14. Berlin: S. Karger, 1921. Pp. 86, 10 plates.

This study presents a detailed investigation of the nature and possible origin of the negroid bodies. The discussion proceeds with a presentation of the history of such study since the discovery of these bodies by Negri in 1903. With these findings and theories of other investigators the authors interweave their own material with which they confirm or question these opinions or with which they open the subject still more widely for future investigation. They explain their own special staining methods and the advantages which these possess. Their work is well illustrated in the ten plates found at the end of the book. Their conclusions tend to the view that these bodies are not parasitic in nature as some have believed but seem rather to be products of vital cell activity presenting a resistance to the invading toxin of rabies.

PSYCHOPATHOLOGY

Der anethische Symptomenkomplex. Eine Studie zur Psychopathologie der Handlung. By Dr. Othmar Albrecht, Privatdozent at the University of Vienna. Abhandlungen aus der Neurologie, Psychiatrie, Psychologie und ihren Grenzgebieten. Beihefte zur Bonatsschrift fur Psychiatrie und Neurologie. Edited by K. Bonhoeffer. No. 12. Berlin: S. Karger, 1921. Pp. 108.

Albrecht presents a stimulating and practical study of action in its intrinsic nature and makes this the basis of a study of pathological "anethical" action. His view is a sympathetically interpretative one of such action as the most natural expression of the ego situated in the midst of certain pathological factors and striving for its own advantageous assertion or reservation of itself. This latter he makes the explanation of the commonly observed negativism. The larger pathological complex may be evident as a distinct disease entity or it may reveal itself only after more careful search into the personality. In any case it demands individualistic research and therapy organic and psychic. One could only ask that the writer had followed up these individualistic features still more interpretatively in the psychic realm. The stimulus of his work, however, leads the reader into the way of such a task.

PSYCHOANALYSIS

Psychoanalysis. By R. H. Hingley, B.A., New York: Dodd, Mead and Company, 1922. Pp. vii-190.

This is a study of psychoanalysis written with thoughtful understanding of the subject by one who knows psychology in the older technical sense of the word. Therefore, he knows the place that psychoanalysis comes to fill as a form of psychology in closer touch with life. He has examined the deviations of thought within the fold of psychoanalysis itself. He presents these in a spirit of fairness with desire to find the working truth and to present the broad active function of psychoanalytical principles applied to practice. His treatment is such as to further knowledge and personal inquiry in regard to psychoanalysis. If he sometimes raises points of criticism which seem to exist only in his own interpretation, that is perhaps the inevitable limitation in any individual criticism. Presented as these are here they should only kindle independent investigation.

CHILD PSYCHOLOGY

Die Liebe des Kindes und ihre Fehlentwicklungen. Ein Buch fur Eltern und Berufserzieher. By Dr. Oskar Pfister, Pfarrer in Zürich. Bern: Ernst Bircher, 1922. Pp. xii, 375.

Pfister always writes interestingly and brings forward a fund of stimulating knowledge and experience. He has done all this here in his culling from the thought of prophet, priest, philosopher and educator their estimate of love and its place in life, particularly in the education of young life. Then he adds his testimony out of his own educational work where he has utilized psychoanalysis and developed its applicability in his particular field of work. He shows by illustrative cases the truth of the theories he advocates that love is the active force in child life both as it lies in its more sexual form at the root of life and as it affords all the capacity for higher developments. The misunderstanding of this love life, the binding of it through inhibitions instead of the training of it through sympathetic instruction concerning it, constitute the basis of disturbances in the child's development. Love must be freed and it must be cultivated through a recognition of its dynamic nature and capacity. The book is so arranged that it is easy to consult briefly but is also rich in content for more complete study.

POPULAR PSYCHOLOGY

Your Inner Self. By Louis E. Bisch, A.B., M.D., Ph.D., Garden City, New York: Doubleday, Page and Company, 1922. Pp. xxi, 195.

This brief presentation of the facts of the mental life, its mechanism and the material which makes use of these mechanisms, is clear and forceful. The brevity of its statements sacrifices nothing of accuracy or clearness of knowledge. Instead the author rouses the reader's interest to seek through personal investigation and personal practice freer use of his mental forces. The book is a very practical revelation of psychoanalysis and the matter which it reveals. The writer speaks from conviction of the important service of psychoanalysis but he has presented the subject in his own specially effective, popular manner.

PSYCHOLOGY

Nerves and Personal Power. Some Principles of Psychology as Applied to Conduct and Health. By D. Macdougall King, M.B. New York, Chicago, London and Edinburgh: Fleming H. Revell Company, 1922.

The author speaks, as in his former book, of a system of philosophy and applied psychology which he himself has put into practice. This book is the message of a man who faced oncoming death without losing his joyous appreciation of life. He discusses in simple understandable terms the bodily organism particularly in its nervous system and its function in the handling of energy for the satisfaction of the organism. He recognizes the fundamental positive values which are the incentives to action and the place which the "moral self" occupies in control of these. His definition of this as his consideration of the instincts, which follows Macdougall, lacks something of deeper interpretation of the force of hidden desire and the need for more analytical search for this. Understanding and control of a disturbed personality is not always so simple as he would seem to say. Yet he does not deny such deeper needs although they are too meagerly mentioned. His point of view is that of the wholesome control of the personality to its best ends through its desires, theoretically a sound viewpoint, practically, as he puts it, full of guidance and stimulus to his readers.

MIDWIFERY

The Threshold of Motherhood. A Handbook for the Pregnant Woman. By R. Douglas Howat, L.R.C.P. (Edin.), L.R.C.S. (Edin), L.R.F.P.S. (Glas.). Glasgow: Kaclehose, Jackson and Company. Pp. 49.

This is an extremely useful little book in which a large amount of valuable information concerning the antenatal and immediate postnatal care of the mother is compressed into forty-nine pages. The book is intended to provide instruction for the pregnant woman herself, and the language and wording are in keeping with this purpose, being expressive, concise, and clear. Technical terms are almost wholly tabooed. The subject is considered from all essential points of view. Sexual physiology is surveyed briefly. An obstetrical table is given by means of which an approximately accurate calculation may be made by the pregnant woman of the date of her confinement. The care of pregnancy is dealt with at some length. The individual symptoms of pregnancy are discussed. The layette and other necessities are described as well as the preparations for the confinement. The confinement itself, the symptoms of its onset, and the technic of delivery in so far as it concerns the woman are entered into and the chapter ends with an earnest advocacy of chloroform anesthesia during the period of labor. The last chapter discusses the measures to be taken with mother and infant just after delivery. The book supplies a need felt among the indigent and cosmopolitan inhabitants of New York and other American cities, as much as anywhere in the socalled civilized world. As the author says, the whole subject of midwifery may be summed up in two words; cleanliness and common sense; and these should be the watchwords of every expectant mother. This small volume is an epitome of midwifery from the woman's outlook and may be commended as such.

HUMAN AND BOVINE TUBERCULOSIS

L'Infection Bacillaire et la Tuberculose Chez l'Homme et Chez les Animaux. Processus d'infection et de defense étude biologique et experimentale. Par A. Calmette. Deuxieme edition. Paris: Masson et Cie., Editeurs, 1922.

Not since the great volume of Prof. I. Straus of Paris, entitled *La Tuberculose et son Bacille,* which appeared in 1895, has there come out a publication of such a character as the work of Prof. Calmette. The book deals with all the phases of the biology of the bacillus, the damage it causes in the animal system, and the natural phases of defense; nearly 650 pages are devoted to these subjects. In the introduction to this remarkable book Calmette pays a graceful tribute to Bayle, to Laennec, to Villemin, and to Robert Koch, and reproduces very good portraits of the three latter. As an American one feels slighted because Theobald Smith, who first distinguished between the bovine and human types of the bacilli, is not placed in this galaxy of pioneers in the study of the biology of the tubercle bacillus. Aside from this omission, one could hardly express anything but the highest praise of this wonderful work.

The book is divided into four parts. The first portion of the volume deals with the bacillary infection and the tuberculous process and in it are given the minutest details of the morphology, the method of finding, coloring, and differentiating the bacillus. A whole chapter is devoted to the isolation and culture of the germ, then follows a description of the influence which physical and chemical agents exert on the bacillus. In the fourth chapter are enumerated the chemical constituents of the bacillus, and then comes what may be considered one of the most complete and important contributions we have on the toxins of the tubercle bacillus (exotoxins and endotoxins and tuberculins). Calmette mentions no less than twenty different products derived from Koch's original tuberculin, among them the three which bear the name Koch, that is T. B., B. E., and A. F., the latter being the one without albumen. Then follow Klebs', Maragliano's, etc., and of course also the neurine tuberculin of Much and the P. T. O. (bovine) of Spengler.

In the remaining chapters of the first portion of the book the author has devoted considerable space to the evolution of the tubercle, its localization, how the virus of the bacillus penetrates through skin and mucous membrane, particularly how the infection is caused in the respiratory organs, glands, and intestines. The pathology of the acute, miliary, and chronic types, and tuberculosis in the aged are given careful consideration. The description of the latter type is particularly interesting. The author very justly says that chronic tuberculosis in the aged is by no means as rare as formerly thought. Its difficult recognition resides in the fact that in the aged the process is insidious and afebrile, and asthmatic and emphysematous symptoms hide the signs of tuberculous lesions; and yet many of these cases take on a very rapid course. Tuberculosis of the pleura, of the meninges, liver, spleen, and suprarenals is described. A special chapter is devoted to lupus, one to bone tuberculosis, and one also to bacillary transmission.

The second portion of the book deals with experimental tuberculosis in animals and gives a description of bovine tuberculosis, its frequency and geographical distribution, and all that is known up to date concerning the communicability of bovine tuberculosis through milk and meat. The third portion of the book contains admirable chapters on how the animal organism defends itself against infection, and on the diagnosis of tuberculosis with the aid of tuberculin. The reactions from tuberculin, such as are obtained by the various skin injections, intradermal, etc., are described. Calmette includes of course his own ophthalmoreaction, and it is somewhat surprising that he still adheres to this now universally abandoned method which was in vogue some years ago, commonly known as Wolff-Eisner-Calmette reaction. He maintains that if one is sure that the condition of the eye is normal, no possible harm can be done and that it is of greatest service in discovering family tuberculosis and thus preventing further development by timely treatment. The lengthy description of the tuberculous antibodies and the rôle they play in the defense of the organism against infection is most interesting. It is impossible in this review to discuss the various opinions of other authors quoted relating to the subject of serum and antibodies in tuberculosis. The student must read carefully all that this able author has written on the subject. It is gratifying that he mentions the admirable work done at the Trudeau Laboratory at Saranac Lake by Kinghorn. Twitchell, Lawrason Brown and Petroff, with which all American students of tuberculosis are familiar.

The fourth and last portion of the book gives a complete review of our present knowledge of natural immunity and the immunization against infection from tuberculosis. One chapter in this portion of the book deserves particular mention, inasmuch as it deals with the chemotherapy in tuberculosis, and it will repay the student to read carefully the results obtained by the use of the salts of calcium, gold, silver, bismuth, arsenic and iodide compounds, salts of thorium and the bromide and sulphate of radium. Thus far it seems that the experiments have been inconclusive and with the rarer salts not encouraging. With the various coloring matters the experimenters have thus far also met with unsatisfactory results, but as the author very well says, this should not be a reason for discouraging further research. Concerning the oil of chaulmoogra, the author admits the encouraging results in the treatment of lepra, but in the treatment of tuberculosis he seems to agree with the opinion of the American experimenters, Biesenthal, Kolmer, Davis and Jaguer, who reported unfavorable results from the use of this oil.

In the concluding paragraph of this highly interesting volume, Calmette summarizes the scientific principles which ought to serve as the basis of the prophylaxis of tuberculosis, and finally says: "The tuberculous infection is so widespread and in certain places so intense that one does not dare to hope for its limitation and subsequent extinction except by vaccination of all men and animals subject to tuberculosis (tuberculisable). This vaccination can be realized because it takes place spontaneously in a number of individuals as the result of one or several light infections and most frequently in the early life. It would be certainly dangerous to produce artificially such infections with the aid of virulent bacilli but we have seen that it is possible to modify certain qualities of the bacilli in such a way that they were no longer able to produce such cellular alterations, characteristic of the tubercle. It is for the experimenter to continue his researches in this direction."

No student who wishes to know the true status of our present knowledge of tuberculosis and its bacillus should fail to study thoroughly this monumental treatise by Calmette. The book is admirably illustrated. It has no less than twenty-five very carefully colored illustrations and thirty-one figures in black. As are all the books published by Masson & Co., so is this work well printed on good paper and solidly bound.

◆

Medicoliterary Notes.

An old book has recently been found in Paris, written by Astruc, consulting physician to Louis XV, in which he states that in 1726 a "charlatan" named Boile "asserts that all diseases are caused by small animals enclosed in the blood," and that each disease is due to different ones of these "animals," that there are other like animals that destroy them, and that there are certain remedies containing these helpful animals so that many diseases can be healed by this "very safe, very brief and very efficient method." Boile, it is reported, fled from Paris upon being accused of charlatanry, for the trial for this offense usually included frightful torture of the accused. Astruc's book sneers at and makes all manner of fun of this crude prophecy of bacteriology, and congratulates medical science upon Boile's disappearance, and that it has been "restored to its former laws."—*New York Times.*

* * *

David M. Neuberger has in a recent issue of the *Outlook* a significant article entitled A Quarter of the Nation's Food Supply in Peril. Pollution of northern waters, both sea and river, by oil, tar, oil sludge and bilge, it is stated, has resulted in destroying or driving away almost all the valuable fish that formerly were so abundant in these regions, especially New England and the North Central States.

* * *

Another study of mankind has just been added to the several published within the last few years. Scribner's has recently brought out as the first of a series of scientific works by leading American authorities a volume by Roland B. Dixon, professor of anthropology at Harvard University, entitled *The Racial History of Mankind.*

* * *

In the *New Republic* for February 14th is an interesting and timely article by Nicholas and Lillian Kopeloff, of the New York State Psychiatric Institute, on The X Ray: Its Use and Abuse.

* * *

The University of Chicago Press has recently announced the publication of a book entitled *The Antiquity of Disease,* by Roy L. Moody.

* * *

The American Red Cross is supervising the transcribing into braille for the blind the Education of Henry Adams. When the volume is completed, it will be sent to the Library of Congress, whence it will be sent anywhere in the United States where it is wished for use by the blind and returned, free of postage. Ex-service men will be granted the privilege of reading it first.

* * *

The work of the Red Cross, through its Health Service in the New York County Chapter, for undernourished children in Manhattan, is outlined in an attractive pamphlet issued from chapter headquarters, 598 Madison Avenue, New York. George R. Bedinger, director of the health service, is the author of the pamphlet. He reports the successful operation of four child health stations and six public school dental hygiene clinics; 1282 children were enrolled in nutrition classes; and more than twenty thousand children were given dental hygiene treatment and instruction.

* * *

Dr. H. Crichton Miller of London has in *Mental Hygiene* for January an article of unusual interest on Psychoanalysis and the School. Doctor Miller prefers to use in the text of his article the term analytical psychology instead of psychoanalysis, and considers its greatest educational contribution is to be made in the field of discipline.

* * *

Public Health Reports for January 12th has for its leading article a report by Surgeon Talliaferro Clark, and Edgar Sydenstricker and Selwyn D. Collins, statisticians of the U. S. Public Health Service, on the much disputed question of Weight and Height as an Index of Nutrition. Another article of interest on this same subject may be found in the *Reports* for November 10, 1922, on Nutrition and School Advancement among Pupils in a Typical Community, by E. Blanche Sterling, acting assistant surgeon.

* * *

During the past few years an interesting experiment in the education of weak and crippled children has been tried out in Vienna, Austria. Large numbers of children were found to be unable to attend school regularly, so all these were collected in a special school to the number of about seven hundred, and were taught occupations suitable to their condition. After care was also provided through regular inspection of homes by trained nurses, and records kept of physical and social conditions to which the child is subjected so that these may be known to the authorities and help rendered when necessary.

Practical Therapeutics

THE TREATMENT OF LOCAL INFECTION BY PHYSICAL MEASURES*

By William Benham Snow, M. D.,

New York.

> "The actual harm resulting from the infection must, to a large extent, depend upon the degree of adaptation to the new condition of life possible on the part, both of the invader and the host."

This truism stated by Zinsser (1) gives the rational clue to the success or failure of the therapeutics of infection, for if the invader finds the field unsuitable from an existing immunity in the host, his existence or growth will either cease or diminish. Or, following invasion, if an antibody is injected which changes the field into one unsuited, harm will be limited or removed for the host. If by other means the body's defences—the phagocytes—in increasing numbers can be induced to assail the infection, the harm will be diminished or cease.

The employment of vaccines so to affect the condition of the host that the invader is destroyed or rendered harmless, has rendered most valuable service in some of the most serious constitutional infections, notably smallpox, diphtheria, cerebrospinal meningitis, tetanus, and typhoid fever, with the number increasing under scientific research.

The physical status of the host as to resistance, idiosyncrasy, or other conditions will vary in different individuals and in the same individual under varying conditions. The condition of the host, therefore, is the unknown quantity in the therapeutics of infection, as it concerns vaccine therapy, particularly in relation to the treatment of pyogenic bacteria. Often brilliant success will follow the use even of a stock vaccine; whereas, very often the employment of most carefully prepared autogenous vaccine will be a complete failure. So often are these results unsatisfactory that intimate friends among the bacteriologists give unfavorable opinions as to the value of vaccines in the treatment of localized infections.

With the use of the physical measures, particularly the forms of radiant energy, it is possible to fortify the resistance and augment the defenses of the host against the invader. Concerning local infections the success of these measures is so uniform as to be relied upon. They actually destroy the invader with the measure employed, afford or induce a greater activity of the phagocytes, or lower the resistance of the invaders, when the phagocytes overwhelm them.

Practical experience during twenty years of investigation has given convincing evidence that local infections succumb more uniformly when subjected to the physical agencies to be described than to vaccines. Local septic infection, which is recognized as serious by physicians and surgeons, has lost most of its terrors to many of the profession who are familiar with the use of radiant light and heat, dry hot air, and other measures in the management of such cases. It is a source of regret that their intelligent employment is not generally understood by the profession.

During the last three decades the clinical employment of the ultraviolet rays, first by Neils Finsen in the treatment of lupus, awakened an interest in the therapeutics of the sun's rays and the electric arc in the treatment of infection. Subsequently the value of the x ray and other forms of radiant energy, including the use of the incandescent lamps and dry hot air were demonstrated. More recently the established value of the ultraviolet rays, as produced in the quartz mercury vapor lamps as a means of destroying germs, was recognized, and later the high frequency currents have made possible the practical treatment of a large variety of infectious conditions.

There are three distinct ways in which germs may be destroyed, 1, by the direct action of an agent which will destroy them *in situ;* 2, by raising the local tissue resistance with the induction of a greater activity and greater numbers of leucocytes or lymphocytes in the field of infection, and 3, by sterilization and inhibition of the activity of the bacteria. These effects are obtained in many practical ways.

Radiant light and heat and ultraviolet rays reflected from luminous sources produce different actions and effects upon pyogenic bacteria, all of which are susceptible to the ultraviolet rays as are all forms of life under varying conditions of exposure. A disadvantage in the use of the ultraviolet rays is that they do not penetrate the skin except when it is rendered anemic by pressure. This was first discovered by Neils Finsen of Copenhagen.

Radiant light and heat reflected from incandescent electric bulbs, preferably from carbon filament lamps, because they produce more heat, will destroy many germs *in situ.* When infection appears near the surface the ultraviolet rays will destroy all germs and fungi when subjected to a few minutes' exposure. Radiant energy reflected from incandescent bulbs, with sufficient energy and long exposures, will destroy the germs in some cases of pyogenic infection, notably the Streptococcus pyogenes. So infections on the surface, and many beneath the skin, will yield to reflected incandescent light either to be destroyed by the light and heat or by the large numbers of phagocytes which come in through the widely dilated vessels. Any measure which supplies heat will induce hyperemia in the tissues of the body, the extent varying with the depth of penetration. The applications of dry heat, radiant light and heat from luminous sources, and diathermy administered from the high frequency electric apparatus, will increase the flow of the blood and increase the presence of the phagocytes—leucocytes and lymphocytes—in the tissues. The increased blood flow through the tissues exposed to the high temperature produce a dual effect, 1, inhibitory to the germs, and, 2, an increase in the number of phagocytes, placing the bacteria more at their mercy.

---

*Read by invitation before the Binghamton Academy of Medicine, April 11, 1922.

Hyperemia is the natural response to the action of any measure that produces heat or cold in the tissues. It is the physiological response to heat or cold. Nature thus protects the tissues exposed to heat and cold from burning or freezing. Hyperemia thus increases the local resistance of the tissues against the extension of heat and cold. So the nose and ears become red in a frosty atmosphere because the blood through the part carries the body warmth to these parts to prevent their freezing, or the hyperemia produced by the heat of the sun's rays with the blood at normal temperatures flowing through the part prevents burning, performing beneficent protection to the part exposed.

When we take advantage of a physiological process to effect a therapeutic result we act intelligently, and, though the hyperemia induced by heat for the destruction of bacteria is not necessarily in accord with the usual performance for local protection, it is invaluable as a means of raising the local tissue resistance, thus enabling us to destroy the bacteria present in an infected part. There are three distinct effects to be derived from hyperemia each of which looks to the improvement of the local tissue resistance: 1, an increased local nutrition; 2, increased metabolism, and 3, an increased number of phagocytes in the tissues. To those who have not thought to employ heat from energetic sources to destroy infection the effects will be reassuring.

The x ray and radium have a specific sterilizing effect upon bacteria which is well illustrated in the treatment of tuberculous and pyogenic infections, as in adenitis, tonsillar and other pyogenic infections, and various fungus conditions, as in tinea tonsurans, and sycosis.

For a long time it has been the custom for surgeons to manage cases of virulent septic infection by employing the antiseptic wet dressing in conjunction with stock vaccines. This may succeed sometimes, but it has often been found to be of little value in the treatment of these cases. Its employment is unfortunate, when there are reliable means of controlling the condition. As a matter of fact, when these patients are put under proper management at the outset and treated on the day when the evidence of the infection appears as a red spot on the surface, an exposure of an hour or two of radiant light and heat reflected from an incandescent lamp, or a four minute exposure under pressure from a mercury vapor lamp, will destroy the germs and terminate the infection. Or when the line marking the extension of the infection along the lymphatics is present, it will often be possible to abort a further extension by long applications of radiant light and heat or shorter ones with ultraviolet rays.

It has been demonstrated that in the treatment of these cases, if not promptly aborted by the exposures as described, they are best managed by the application of dry hot air applied at as high a temperature as can be tolerated in an apparatus constructed for the purpose. Such apparatus or ovens are heated by gas or electricity. Place the arm or leg infected, after properly wrapping it, in the apparatus and employ a temperature of from 300° to 500°F. The part to be treated is first wrapped in several layers of Turkish towelling to prevent the accumulation of perspiration upon the surface which would boil and blister the skin. It will surprise those not familiar with the method how well high temperatures are so tolerated.

This is a practical method of treating the worst cases of local septic infection. The part should be placed in the oven daily for at least one hour. Dry heat employed in this way will produce a very active hyperemia in the skin and underlying tissues; whether it is the heat or the phagocytes or both that destroy the germ, it is hard to say, but probably the latter. The blood flowing rapidly in and out through the part probably is never but a few degrees above normal. The extreme degree of heat, however, so far inhibits the bacteria that they are an easy prey to the leucocytes, for from the first administration the process is always checked.

During the past twenty years we have treated in our offices very many of these cases and without a single failure. A few case reports will illustrate the routine and success obtained with the method.

Case I.—Mr. R. was referred to our office by a resident physician with an arm that had been infected for several days. Incisions had been made in a number of places along the arm and forearm for evacuations of pus. This patient was given three succeeding applications of dry heat, applied for one hour each day, when all evidence of the infection had disappeared and the incisions promptly healed.

Case II.—A physician, who came to us, will illustrate the futility of other methods as compared with those which I have outlined. Dr. M., a surgeon from Toronto, Canada, came to us with an infected hand from which he had been suffering for two or three months. He had gone to a well known clinic in Minnesota seeking relief, and was advised to leave it to Nature, but the *vis medicatrix naturæ* had proved ineffective in his case. When we examined the hand it was found that the tendons were not adherent in the sheaths, though the hand had been incised at three places on the dorsal surface. There were two discharging sinuses on the back of the hand, and the end of the index finger had sloughed back to the bone end. The hand was swollen, stiff and useless. We gave him administrations of dry heat on five successive days, and in the intervals between treatments prescribed the use of the reflected incandescent light over his arm and hand for one hour twice daily. Massage, passive motion and exercise were employed. In three weeks he was able to return to his surgical practice with a useful hand.

These cases illustrate the methods and the success attained by a rational treatment of a form of infection from which several surgeons have lost their lives during the past year. Each year adds to the roll, and yet they persist in the use of wet dressings.

In 1910 we treated the first case of erysipelas with incandescent light making the exposures for one and a half hours, as intense as the skin would bear. The treatment was so effective that I was inclined to doubt my diagnosis, but results obtained in subsequent cases and reports from others have confirmed it.

The following case reported by Dr. James R. Bingham, of New York (2), will illustrate the measure of success obtained even in a very bad case, treated by an eminent surgeon:

CASE III.—"A case of facial erysipelas, which had received no treatment for several days after its inception, and therefore was well advanced. One eye was entirely closed by the swelling, and the other nearly so. All the features of the face were practically obliterated, and one ear was very badly swollen and painful.

"I had the light applied for an hour's duration, five or six times the first day, and twice during the first night, as the patient was wakeful. During the second day the light was applied less often, and for shorter periods, and as the patient slept all during the second night it was not applied at all.

"From the beginning the pain was markedly relieved by each treatment, and after the first day there was absolutely no pain complained of by the patient.

"The swelling and redness began to recede from the first application of the light, and at the end of forty-eight hours the only manifestation of the disease remaining was a slight swelling of the involved ear, which entirely disappeared on the third day after a few short applications of the light."

In the winter of 1919, Dr. M. M. Thompson. Captain, M. C., of Pitcairn, Pa., in charge at the Port of Embarkation at Hoboken, when handling gonorrheal cases became infected in one eye and the surgeons diagnosed the condition as gonorrheal ophthalmia. On hearing of his predicament I at once ordered a fifty candle power therapeutic incandescent lamp sent to the hospital. The surgeons had put him to bed, and he was suffering excruciating pain from the infection. When the lamp arrived he applied it as hot as he could stand the radiations, and reported that after half an hour's application the pain had ceased. He adjusted the lamp on a stand at a distance from the bed at which he could tolerate the heat and lay with the light shining upon his eye for the whole night. In the morning when the surgeon came to his room he found the patient's eye was open and free from pain though deeply injected. The surgeon asked what he had been doing. He pointed to the lamp, and the surgeon remarked, "We are never too old to learn." He continued the use of the light for three days, after which time the eye was normal. I believe that this was the first case of gonorrheal ophthalmia treated in this manner.

Three other cases have been reported, and published. One by Dr. M. M. Thompson (3); one by Dr. Lois L. Gannett (4); and one by Dr. F. S. Holladay (5).

To report the cure of such infections as erysipelas and gonorrheal ophthalmia by a measure so readily at hand, to a medical body who may not have previously seen reports of these methods, is presumptuous in the face of recognized medical conservatism, but I could not resist the opportunity; for there is no doubt that the results will be confirmed, as the cases were correctly diagnosed. I, therefore, urge in the interest of humanity that they be investigated and not neglected; because they are unusual.

ACNE AND FURUNCULOSIS.

The treatment of acne and furunculosis and other infections with the x ray is now an established method recognized by the dermatologists everywhere. In simple acne the same method is employed and the advantage of the x ray in these cases is that it causes contraction of the skin and so closes the openings of the sebaceous glands and prevents the formation of comedones.

ADENITIS.

The treatment of tuberculous adenitis with the x ray is also now an established method. When there is no pus or caseous formation which would require evacuation and curettage, diathermy and the x ray will cure these cases with great promptness.

The treatment of enlarged and infected tonsils and adenoids is the latest recognized forward step in x ray therapy. The method of Byron S. Price, (6) and that of Dr. W. D. Witherbee (7) and others confirm the value of the method. Personal experience further confirms the prompt cure of those cases with the x ray.

OTITIS MEDIA.

Radiant light and heat in cases of purulent otitis media are uniformly successful as was first shown by Dr. Herbert F. Pitcher. One hour applications with the lamp suspended at a distance at which the patient will tolerate the heat over the ear and mastoid given daily, will often abort an acute case and within two or three weeks will cure the chronic cases.

FRONTAL SINUS INFECTION AND CORYZA.

The use of light in these conditions, with one hour daily exposures, as in otitis media, prolonged as in the former. In the first stage of coryza, two or three one hour applications within thirty six hours at twelve hour intervals in healthy patients will often cause a disappearance of all the symptoms.

PLEURISY AND BRONCHITIS.

Acute pleurisy and acute bronchitis are successfully treated with diathermy employing the high frequency current by placing a large metal electrode on the anterior side over the chest and one on the posterior side, or on the opposite sides, employing the current as hot as can well be tolerated by the skin for one hour daily. Relief is immediate, as a rule, relieving all symptoms in two or three days. Chronic cases are treated by the same method but take a longer time to effect relief.

PNEUMONIA.

There are no records yet of cases of pneumonia in which this method has been used, but there is no reason to doubt that diathermy is indicated, at the outset, before consolidation has occurred. If diathermy is applied with proper energy, in the future these cases may be aborted. Long applications of radiant light and heat have proved remarkably effective in pneumonia.

CHOLECYSTITIS.

In cholecystitis there is no remedy that will give as much satisfaction in our experience as the employment of diathermy.

Clinical experience after all is the actual index of therapeutic efficiency, and the physical therapeutic laboratories are revealing truths based upon an actual scientific basis that already rival the bacteriological laboratory methods in the therapautics of infection.

Letters to the Editor.

THE TREATMENT OF INFLUENZA

New York, *February* 20, 1923.

To the Editor:

I have found nothing better than the mixture I have previously recommended, consisting of ammonium salicylate, gr. lxxii; caffeine, gr. vi; essence of pepsin, ʒi; water, ℥vi. Of this I, at present, give a tablespoonful every hour for three or four hours, and thereafter a dessertspoonful. For the sake of convenience, in many cases, I give the remedy in capsules instead of solution, and I then omit the pepsin. At bedtime I give aromatic spirit of ammonia and sweet spirit of nitre. I then stop the salicylate mixture. If there is cough and fever, I start warm creosote inhalations from a croup kettle, with or without compound tincture of benzoin. I use benzoin only when objection is made to the smell of creosote.

There is no specific against influenzal pneumonia, but what I have outlined will help prevent it in a measure and will greatly modify its seriousness many times. Good whiskey, black coffee and strophanthus in small repeated doses, will save life, if any treatment will.

Fear of contagion is a bugbear which should not be tolerated. It is lack of knowledge which makes it prevail. Personal immunity is something the wisest physicians do not as yet understand; I mean the why and wherefore.

Beverley Robinson, M. D.

X RAYS

New York, *December* 26, 1922.

To the Editor:

Your editorial X Rays in Diagnosis, appearing in the issue of December 20, 1922, moves me to submit the following reply:

The advantages of an x ray examination of the chest for suspected tuberculosis have been amply demonstrated by radiologists who possess the necessary technical training in this special field of medicine. But it should not be expected of the radiologist to render an absolute diagnosis in those cases which so often puzzle a skilled clinician.

Numerous signs such as the hazy outlines of an active apical infiltration, studding of the bronchi in slow perihilar dissemination, the wedge of dilated vessels or lymphatics, with the apex at the hilum, form parts of a chain that helps to make up the phenomena which the radiologist must learn to recognize and, at the same time, must assign to each its proper importance and interpretation. In many instances repeated examinations are necessary to clear up the diagnosis in suspected cases of early tuberculosis. The chest must be examined with due regard to the possibilities of finding a lurking foci in the mediastinal glands or somewhere in the pulmonary parenchyma. Caseating paratracheal glands or an inverted comma may often be the only suspicion of a beginning tuberculous process. Or, again, a focus of infection may be obscured by superimposed shadows or by the persistent sequelæ of obsolete lesions. To uncover a mask of this type examinations made in the ventrodorsal, dorsoventral, right lateral and left lateral positions are necessary. Even then a group of cases defies the most careful scrutiny with both fluoroscopy and röntgenograms and can only be differentiated by the combined efforts of the clinician and the röntgenologist.

It is only expedient to check the results of radiography by the usual means of diagnosis. Perhaps this is what the editor means when he speaks of pictures "taken with considerable salt"; on the other hand, however, röntgen diagnosis alone has proved decisive. I am sure that the editor cannot mean to eliminate the advantages which the competent röntgenologist can offer the clinician. The clinician and the röntgenologist can cooperate and make each method the complement of the other.

Herman Besser, M. D.

EPIDEMIC ENCEPHALITIS

New York, *February* 16, 1923.

To the Editor:

Epidemic encephalitis (lethargica) is in our midst again. Owing to the fact that we have no definite specific remedy as yet, I should like to stress the use of nonspecific therapy in this disease. Simply to treat those afflicted, symptomatically, is not, in my opinion, using all our armamentarium.

The use of skimmed milk, according to Döllkin, has not shown uniformly consistent results. Then again, it cannot be graded according to reaction, etc. The omnicellular theory of Weichhardt, and its application to the treatment of epidemic encephalitis, is to be preferred to that of Döllkin and his coworkers.

Both on the neurological service of Dr. William Leszynsky, at Lebanon Hospital, and in my own practice, we have used sodium nucleinate very effectively in the acute as well as in the subacute type of this disease. The physiological and pharmacological effects of this protein on the body and the blood is well known—stimulation of the entire organism, with the increased production of leucocytes and their phagocytic action, together with the increase of the antibodies. Then again, in the histopathology of epidemic encephalitis, the virus does not arouse a reaction sufficient it seems to produce antibodies, which makes the use of this substance highly desirable from this viewpoint.

We standardize the solution, using sterile water, so that one grain equals five minims of the solution. It is used subcutaneously. Each case is judged by itself, as to how much should be used, particularly the initial dose, in view of the severe anaphylactic phase that often follows. In cases presenting a temperature above 102° F., one should start with a half grain, and then work up.

At Lebanon Hospital we use the blood reaction as an index, particularly in the subacute stage. In the acute stage the temperature and the general aspect of the individual must be taken into consideration as a guide for reaction. In the blood examinations we naturally take the total white and differential before and after the administration of the protein. Six injections was the highest number used, and it was in a case that should have gone on to be a classical case of Parkinson's disease type, by all the rules of this disease. The patient has been back to work as a letter carrier for nearly a year. What the future will show I cannot say.

Joshua H. Leiner, M. D.

Abstracts from Current Literature

MALIGNANT GROWTHS.

Radiotherapy in Cancer.—G. E. Pfahler (*International Journal of Surgery,* December, 1922) gives the following summary: Radiotherapy, when practical, should be used preceding and following operations. Electrocoagulation can, in many instances, be used to advantage to replace excision, because the bloodvessels and lymphatics are sealed off in the process of destruction and there is a heat zone beyond the area of actual destruction which will destroy carcinoma. Radiotherapy can be used with success in nearly all superficial cancers. Radiotherapy will in some instances cause a complete disappearance of even deep seated malignant disease. If it is known that cancer can be cured by radiotherapy, disastrous delays on the part of patients will be avoided. Skill is required in the use of radium, x rays and electrocoagulation, just as skill is required in surgery.

Treatment of Breast Cancer.—F. E. Bunts (*Annals of Surgery,* September, 1922) concludes that the successful treatment of cancer of the breast, as of any other pathological condition, should be strictly individualized. The ultimate sequelæ depend more upon the stage and dissemination of the growth when it is presented for treatment than upon any defined method of operation. Greatly increased data regarding the value of the preoperative and postoperative use of the x ray and of radium are required before final conclusions can be drawn, although there seems little doubt of the value of radium applied directly in the axilla. The substitution of the x rays or of radium for surgical treatment cannot safely be considered at the present time. The early removal of any growth remains the one and only sure method of treatment.

Cancer of the Breast. Treatment of the Proemial Breast.—G. Lenthal Cheatle (*British Medical Journal,* June 3, 1922) calls attention to a potentially dangerous state of the breast and indicates the advisability of the removal of the breast while still in this state rather than later, when surgery gives unsatisfactory results. The reasons for the failure of surgery in primary, clinically recognizable cancer of the breast are: 1, its insidious onset, giving no symptoms until the disease is too far advanced for a cure; 2, the patient does not always seek medical aid early enough; 3, the present five year period of quiescence is too short; 4, the clinical symptoms do not always coincide with the malignancy or the benign character of a tumor. It is therefore advisable to deal adequately with breasts in which cancer or papillomatous growths are likely to occur and not to wait for definite signs. Such a condition of the breast is called the "proemial breast."

Not every nodular breast is pathological, as most adult female breasts, unless there is much fat in them, are multinodular, the nodules being prominent mammary ducts, recognizable by careful palpation or the direction of the ducts, the ducts becoming smaller toward the periphery of the gland. The proper method of palpation is to support the pendant breast with one hand and to palpate with the fingers of the other. It should be remembered that painfulness may be due to a physiological vascular turgescence. The proemial breast is worthy of due recognition for two reasons: 1, it is a forerunner of further pathological changes, such as simple papillomata, malignant papillomata and other forms of cancer; 2, its recognition and proper treatment aid the surgeon in recognizing (microscopically) possible malignant changes sooner than in any other way. When once established, the condition of the proemial breast is permanent.

Clinically, there is pain in the breast at an age of forty to forty-five years, occasionally severe, persistent and continuous. Both breasts may be nodular, but in the diseased breast the nodules are swollen, painful and tender and of unequal sizes in corresponding parts of the gland; the swollen nodules are composed mainly of prominent ducts. Segments of the gland or the whole gland may be affected. There may be an intermittent or continuous discharge from the nipple, or a thin layer of coagulated serum on the surface of the nipple, always small in amount. In the later stages the pain disappears and cysts are formed. Severe massage may induce a thick, white discharge from the nipple, containing desquamated epithelial cells, but this should not be done because of the possible presence of cancer and its consequent dissemination. Frequently cases diagnosed as proemial breasts show the presence of a malignancy. The treatment in every stage is removal of the breast with dissection en bloc of the fascia over the pectoralis major muscle with the lymph nodes attached. The removed breast should be carefully and thoroughly examined microscopically for the presence of cancer and if found, the skin covering the breast, the pectoralis major and minor muscles and the parts around the axillary vein should be completely removed.

Radiotherapy in Carcinoma of the Breast.—George E. Pfahler (*Surgery, Gynecology and Obstetrics,* August, 1922) concludes that it has been shown that thorough radiation treatment of cancer tissue will devitalize the cancer cells so as to interfere with their inoculation or further development. This justifies our recommendation of anteoperative treatment. It has also been shown that radiation effects are most evident on new growing tumor and such radiation will prevent the growth of inoculated tumors. Therefore, we recommend active postoperative treatment in cancer of the breast. Visible and palpable recurrent metastatic cancer are probably only an index of similar disease elsewhere, and therefore, the treatment of these cases should not be confined simply to the palpable and visible disease. Such visible and palpable disease should receive the most active treatment and sufficient to cause its destruction and disappearance. Thorough radiation treatment will cause the disappearance of tumor tissue in some cases and, therefore, can be recommended when there is any reason for avoiding an operation. In every case of cancer of the breast there should be an x ray examination of the chest, and this should be repeated from time to time to detect any possible invasion of the mediastinum or lungs, sternum, or spine.

Carcinoma of Breast.—Burton J. Lee (*Annals of Surgery,* September, 1922) emphasizes the following points: Primary inoperable carcinoma of the breast has shown good results by radiation. The patient must be kept under constant clinical observation. The type of radiation must be properly selected for each individual case. No routine prescription will suffice. Overtreatment by radiation must be avoided. Very advanced cases are unsuitable for any form of treatment. The palliative operation following properly planned radiation is of service in well selected cases. A cooperating social service department makes a followup system effective and gives humanitarian relief to the hopeless cases. The results to date are gratifying and encouraging. As the disease itself and the technic of radiation become better understood, we believe that more and more satisfactory results will follow.

A Review of Three Hundred Cases of Breast Disease.—The material upon which this review by Irvin Abell and Stuart Graves (*Southern Medical Journal,* May, 1922) is based consists of three hundred cases coming under observation up to and including 1920. Two of these were of sarcoma, 138 of carcinoma, and 160 of various types of benign disease. Of the 138 carcinomata 136 occurred in women, 100 were in married women, 36 in unmarried. The youngest patient with carcinoma was twenty-six; the oldest seventy-eight. The following operative results were obtained: Number of cases of carcinoma operated in, 110; number of patients living and well, 49—44.5 per cent.; number of patients known to be dead, 34—31 per cent.; number of patients dying in hospital (operative mortality), 4—3.6 per cent.; number of patients dead "cause unknown," 11—10 per cent.; number of patients dead "recurrence," 19—17.4 per cent.; letters to carcinoma patients returned "unopened," 12—11 per cent.; letters to carcinoma patients "unanswered not returned," 10—9 per cent.; number of patients living but having recurrence, 5—4.5 per cent.

Carcinoma of Rectum.—J. R. McVay (*Annals of Surgery,* December, 1922) asserts that rectal carcinomata are the most common form of intestinal neoplasms and make up four per cent. of all the cancers of the body. The majority of patients are in the sixth decade. The males predominate slightly. The location of the growth on the rectal wall varies. About as many occupy the anterior wall as the posterior. The greater number of the growths are from the ampulla to the rectosigmoidal juncture. Adenocarcinoma is the most common type. Metastasis to the glands usually takes place slowly and the liver is the organ most affected by secondary growths. The other organs of the body are only rarely affected. The size of the growth in the rectum cannot be relied on as an accurate index of the probable lymphatic involvement. The growths without lymphatic involvement tend to grow into the lumen of the bowel. The growths with slight lymphatic involvement tend to spread by direct extension and are slow growing. Carcinomata of the rectum with extensive lymph glandular involvement tend to metastasize through the lymph stream early. Occasionally metastasis may take place by emboli breaking off into the portal veins. Metastatic lymph glandular involvement can only be definitely determined by systematic microscopic study of all the regional lymph nodes. The size of the lymph node is not an efficient means of determining whether or not there is metastatic involvement. This is especially true if the amount of involvement is small, or if the process is an early one. Systematic microscopic examination of all the regional lymph nodes in carcinoma of the rectum offers, as it does in cancer of the stomach, the best method of establishing an accurate prognosis for the case.

Metastasis in Massage in Malignant Tumors.—L. C. Knox (*Annals of Surgery,* February, 1922) concludes: Study of human material in many ways suggests, but does not finally prove, the importance of massage as a means of inducing metastasis of tumor cells. In animals, on the contrary, very gentle massage for a total period of from two to five minutes, distributed over a number of days, has been shown to set free numerous particles of tumor which form emboli in the lungs. Such emboli produce metastatic tumors in a variable proportion of instances, depending upon the growth activities of the tumor. Tumors which take in low percentages when implanted in the subcutaneous connective tissues give much fewer metastases than those of high virulence. Carcinomata and also sarcomata of the loose polyhedral cell type are easily generalized, but sarcomata of the compact spindle cell variety are not influenced. The importance of avoiding diagnostic or operative manipulation of a tumor in man is obvious.

Swelling of the Arm After Operations for Cancer of the Breast.—William Stewart Halsted (*Bulletin of the Johns Hopkins Hospital,* October, 1921) concludes that swelling of the arm follows the plastic operations in greater proportion and in more pronounced form than is seen in the cases of cancer of the breast treated by skin grafting. In the skin grafting operations at Johns Hopkins Hospital, conspicuously swollen arms have become almost a thing of the past after the method of pressing back the flaps at the upper part of the wound and stitching their edges to the underlying costal muscles was adopted. A search of the records of Johns Hopkins Hospital for cases of swollen arm following carcinoma of the breast supports Halsted's view that infection is frequently, if not usually, the overlying cause of the swelling of arms whose main lymphatic channels have been blocked by operations.

Sarcoma of Long Bones.—H. W. Meyerding (*Surgery, Gynecology and Obstetrics,* March, 1922) from his studies summarizes as follows: 1. Thirty-five per cent. of the cases were inoperable or patients refused operation. In many instances early diagnosis would have given the patients a chance for cure. 2. Thirty-two of the thirty-five patients who died had amputations. The average duration of the disease at the time of their examination was 7.34 months, and they lived an average of 14.5 months after operation. The average duration of life of the thirty-two patients was 21.9 months. One patient who had a fibrosarcoma was examined nine months from the onset of the disease and lived thirty-six months after operation, a total of forty-five months, the longest duration of life in those who have died following amputation. 3. The most malignant sarcomata in the series of thirty-two patients were the osteosarcomata. Eight of these patients, the average duration of whose symptoms was 2.5 months before examination, lived seven months after operation, a total average of 9.5 months. 4. Ten patients have died who had had excision and cautery. The average duration of symptoms was 6.6 months, the average duration of life after operation, 28.2 months, and the average length of life from the time of the onset of symptoms, 34.8 months. One patient with osteosarcoma, who was examined two months after the onset of the disease, died six months after a local operation. Five patients treated by excision and cautery died of pulmonary metastasis. 5. Twenty-one (31.8 per cent.) of the sixty-six patients in the series who had amputations are reported to have died of metastasis to the lungs. The average length of life of these patients was 21.9 months. 6. The value of microscopic proof of malignancy of tumors of the long bones is obvious, inasmuch as the fate of an extremity may depend on such proof. If any doubt exists with regard to the character of the tumor, section from various portions should be examined. 7. A diagnosis should be made only after thorough clinical, physical, and röntgenographic examinations have been made, and even then cannot always be determined until an exploratory operation and microscopic examination rules out giant cell tumor, chondroma, fibrocystic or cystic disease, syphilis, and osteomyelitis. The principal points to be decided before operation are malignancy, metastasis, and the extent of bone involved. With early diagnosis, with eradication of the tumor, with care to exclude patients with metastasis, and with the use of radium, röntgen ray, and Coley's toxin, prolongation of life may be looked for following operation.

Changes in the Esophagus with Lymphosarcoma and with Lymphogranuloma of the Mediastinum.—Martin Haudek (*Wiener klinische Wochenschrift,* June 8, 1922) reports two cases. The first case showed penetration of a lymphosarcoma into the esophagus, which was demonstrated röntgenologically and with the esophagoscope, and the second case showed dislocation of the esophagus and trachea by a mediastinal tumor.

The first patient was a female, twenty-three years old, who for several weeks noticed dysphagia associated with a generally run down condition. Both sides of the neck showed lumps of lymph nodes. The röntgenogram showed very large masses in the upper right mediastinum, overshadowing the heart; the esophagus was pushed to the right and backward and there was a stenosis above the bifurcation of the trachea. The diagnosis of extensive adhesions of the mediastinal tumor with the esophagus and a penetration of the same into the wall of its lumen was made. This finding was confirmed by esophagoscopy. The necropsy showed a colossal dilatation of the esophagus, such as rarely occurs even in carcinoma. The röntgenogram showed the combination of the characteristic features of all the processes which affect the esophagus: 1, dislocation by a tumor pressing from without; 2, a coarsely irregular contour of the shadow of the stenosis usually found in obturative stenosis (carcinoma of the esophagus); 3, the fractional diverticulalike processes of the contrast shadow. There was also a characteristic stippling of the contrast shadow.

The second patient was a man, fifty-six years old, who took sick with multiple glandular swellings. A lymphogranulomatosis was diagnosed at first, but the use of x rays changed the condition so markedly that a diagnosis of glanuloma was made. The mediastinal tumor and the glandular tumors of the axilla and neck disappeared entirely. The röntgenogram showed a dislocation of the esophagus by compression from without, an irregular contour of the shadow, as is seen in a process involving the walls and displacement of the esophagus as in periesophagitis. The absence of dysphagia showed that the subjective symptoms and the objective findings do not always go hand in hand in the esophagus.

NEUROLOGY.

Anatomy of the Cerebellum. — S. Ingvar (*Hygeia,* December 16, 1922) concludes, after an exhaustive study of the anatomy of the cerebellum, that this organ instead of being a motor organ as is often held, depends in a marked degree upon the peripheral impulses it absorbs, just like all other reflex organs. The cerebellum is an organ of equilibrium, that is to say an organ which to preserve equilibrium, a dynamic postulate for all creatures, succeeds in neutralizing and influencing by reflex action, the static and kinetic forces surrounding us due to the physical laws of gravity, etc. The author mentions Ramsay Hunt, of New York, and Walsh, of England, as sharing his views. Everything seems to point toward the fact that the afferent peripheral impulses, upon which the reflex activity of the cerebellum depend, are of an exclusively static and kinetic nature. As the physical laws of gravity, etc., are common and identical for all, it is comprehensible why the cerebellum in all vertebrates offers not only the same histological picture but also develops according to the same morphological stages.

A Case of Localized Suppurative Meningitis Over the Motor Cortex.—C. P. Symonds and W. H. Ogilvie (*Lancet,* August 5, 1922) report a rare case of a sharply localized patch of suppurative meningitis over the motor cortex, separated by at least two inches of healthy tissues from the source of the infection—the middle ear and mastoid process. The mastoid process was in an early stage and the obvious bone disease affected only that part of the mastoid process furthest away from the cranial cavity. From the surgical viewpoint there were three routes of infection: 1, the labyrinth and internal auditory meatus; 2, the diploë of the squamous temporal bone, and, 3, the direct spread through the subarachnoid space. The first route may be definitely excluded by the absence of corresponding symptoms. If the disease had spread by the second path, there would have been visible infection of the diploë in the squamous temporal bone and a localized patch of infected dura, neither of which was present. The bacteria probably traveled from the middle ear to the motor cortex via the lymphatics of the bone, the dura and the subarachnoid space, but the resistance of the intervening tissues was great enough to prevent any manifest infection. Neurologically the main facts of interest in the early history of the case are the completeness and sudden onset of the brachial monoplegia in relation to quite a superficial cortical lesion and the absence in the early stage of focal epileptic attacks, which only supervened as a penultimate phase preceding the recovery of voluntary power. This sequence of events is the exact reverse of that seen in progressive destruction of the motor cortex by a meningeal tumor. Taken together, these two observations show that the epileptic discharge depends upon a condition of the motor nerve cells, which lies somewhere between the two extremes of normal activity and complete inexcitability. In this case this optimum point for an epileptic discharge may be passed before a seizure has had time to mature. The lesion probably affected the anterior part of the postcentral convolution in its lower half.

Epidemic Encephalitis.—C. Kling (*Hygeia,* 84:894, November 15 and 30, 1922) concludes from his experiments that: Experimental herpes encephalitis is of quite another character than epidemic encephalitis in the rabbit. The characteristic symptom of the herpes virus, purulent keratoconjunctivitis after inoculation of the cornea, is missing when the encephalitis virus is used. The convalescent serum of encephalitis has a neutralizing action in vitro on the encephalitis virus but not on the herpes virus. The hitherto undertaken experiments in immunity point to a marked difference between the two. In studying the epidemic in Sweden, the author was impressed by the number of abortive cases and suggests the possibility of the disease spreading through carriers who are in good health themselves. The chronic forms, of a progressive character with alternating remissions and relapses, have been found to show symptoms of various nervous diseases, the etiology of which has hitherto remained obscure, i. e., Sydenham's chorea and even simple chorea. Huntington's chorea and chorea electrica have been looked upon by some authorities as sporadic types of epidemic encephalitis. Parkinson's disease is considered by some as nothing other than a chronic manifestation of the encephalitis virus.

Toxiinfectious Lesions in the Central Nervous System.—David Orr and A. Corsar Sturrock (*Lancet,* August 5, 1922), from a series of experimental investigations into the influence of disturbances of the sympathetic mechanism on the localization of these lesions, draw the following conclusions: 1. Sympathetic division alone produces vascular dilatation, perivascular edema, slight proliferation of adventitious cells, which may be a response to increased permeability of the vessel wall from sympathetic paresis and the release of certain noxious products from the circulation; also morbid nerve cell changes. The areas affected were those supplied by the pial vessels: the cornu ammonis and fascia dentata, the caudate and amygdaloid nuclei, the pyriform lobe and the cortex cerebri. 2. Division of the cervical sympathetic is followed by a general intoxication and the lesions are found in the same areas but in a much greater degree and the unilateral division of the sympathetic intensifies the toxic morbid lesion on the same side. The areas involved in both experiments were the archaic regions of the brain and the cerebral cortex. These are all supplied by the pial vessels (under sympathetic control). It would appear, therefore, that the sympathetic nervous system is an important factor in toxiinfective inflammation and degeneration and its involvement is a contributory factor in the localization of lesions, not only in the central nervous system, but probably wherever they may occur. 3. The periarteritis in the head of the caudate nucleus is so well defined and so localized as to seem of special significance; this area is in direct communication with the basal cortex and therefore with pial supply. 4. The lipoid secretion in the ventricles and choroid plexus is an active process, as shown by the intense and early secretion of the lining epithelium; it is a protective as well as a regenerative mechanism. 5. The lesions described above show definite changes in the archaic areas and cortex and are produced through interference with the blood supply without toxic influence, although the additional intoxication intensifies the reaction. A healthy circulation is essential for the maintenance of balance of the various reciprocating portions of the nervous system and a healthy psyche depends upon it to a great extent.

Venous Angioma of the Cerebral Cortex.—Charles A. Ballance (*Lancet,* July 15, 1922) reports a case of angioma of the cerebral cortex which is one of the rarest of brain tumors. The interesting features of this case were the following: 1, The sensory aura beginning in the face; 2, the absence of any change in cutaneous sensibility; 3, the absence of optic neuritis; 4, the extremely large size of the veins forming the angioma; 5, the marked improvement following operation—presumably due to the relief of the local pressure. As this condition, undoubtedly, was congenital, it is remarkable that the increase in size, which is a common feature of these tumors, did not produce symptoms until the age of twenty-seven. This case, together with two others previously reported, showed the following features in common: 1, epilepsy as the first symptom with a relatively slowly developing hemiplegia; 2, epileptic attacks of the Jacksonian type, preceded by a definite trauma; and, 3, the absence of optic neuritis.

Relationship of Syphilis to Diseases of the Central Nervous System.—Francis M. Barnes, Jr., (*Medical Clinics of North America,* July, 1922) concludes that syphilis of the central nervous system may produce clinical pictures which, casually, may easily be confused with almost any other disease of the central nervous system and this, even after the most careful study and investigation. Wherever there is a possible underlying factor of syphilis, in any disease of the central nervous system, adequate antisyphilitic treatment should be given. However, the therapeutic test is not ultimately final and syphilis cannot be excluded simply because a patient supposedly syphilitic does not respond to antisyphilitic measures.

Zinc and Copper Content of the Human Brain.—Meyer Bodansky (*Journal of Biological Chemistry,* October, 1921) found in the analysis of one fetal and four adult brains that copper and zinc are normal constituents of the human brain. The analysis of the fetal brain suggests that during intrauterine life there is more rapid storage of zinc and copper in the brain than there is after birth, the behavior of these elements being in this respect similar to that of other inorganic constituents of animal tissues, such as iodine, sulphur, and phosphorus.

GASTROENTEROLOGY.

Focal Tenderness in the Diagnosis of Gastric Ulcer.—George Vilvandré (*Lancet,* May 27, 1922) lays great stress on the value of focal tenderness obtained by palpating with one finger along the whole of the lesser curvature, from a point near the cardia, starting from the infrachondral margin, down as far as the pylorus. In doubtful cases pressure with the tip of the index finger elicits definite pain over the region of the ulcer. This sign is not found when the patient lies on his back, but only when he stands upright. This pain may occur on palpation even without the presence of spontaneous pain. The stimulus is definite at a given point, repeatedly obtained, rapidly disappearing and sharp. It is not found in chronic lesions, the nerve endings being destroyed by ulceration.

Death in Intestinal Obstruction.—J. W. Ellis (*Annals of Surgery,* April, 1922) concludes that from the intestinal content in cases of high obstruction, a poison can be isolated by precipitation with alcohol, extraction with boiling water and reprecipitation with the aid of magnesium sulphate. It is not possible to obtain such a poison with this method from the intestinal content of a normal dog prepared immediately after removal. A poison which, when judged by the means at our disposal, is identical, can be obtained from conditions other than actual obstruction, such as the intravenous injection of the high obstruction toxin into normal animals, the removal of the adrenals, portal obstruction, and in experimental, acute, fulminating, nonbacterial peritonitis. This poison is undoubtedly elaborated in the cells of the greater part of the mucosa of the small intestine, but chiefly in those of the duodenum, and is manifestly excreted, partly into the lumen of the intestine, but the larger part passes into the lymph stream. The clinical similarities between acute pancreatitis and high obstruction are due either to a close relationship between the toxins involved, or possibly to the fact that acute pancreatitis actually produces conditions in the intestinal mucosa favorable to the production of the same toxin, as is found in cases of high obstruction. Since erepsin fails to exert any action upon the toxin, and since the toxin shows no lymphagogic action whatever, it seems necessary to conclude that the toxin is neither a proteose nor a heretoproteose. The clinical advantage of gastric lavage may be explained by the removal of the toxic content and the favoring thereby of an increased excretion into the lumen of the intestine. To this treatment should be added the introduction of large amounts of saline, both intravenously and by the rectum, to further the excretion of the toxin both by the bowel and by the kidneys. The finding of the toxin in the intestinal content after the removal of the adrenals suggests that clinically adrenalin should be added to the saline infusion in sufficient amount so that a continuous supply of adrenalin is being furnished.

Foreign Bodies in the Duodenum.—In a series of fifteen cases of foreign bodies in the digestive tract, Waldemar Goldschmidt (*Wiener klinische Wochenschrift,* August 3, 1922) found the duodenum to be the most frequent portion of the digestive tract (below the stomach) in which the foreign body was arrested (twice in the stomach, five times in the duodenum, four times in the small intestine, twice in the cecum, once in the hepatic flexure, three times in the transverse colon, once in the sigmoid and four times in undetermined locations). The duodenum is not only the site of the most frequent arrest of the foreign body but it is also the site of the most frequent perforation.

The X ray in the Diagnosis of Certain Gastroenteric Lesions.— Lowell S. Goin (*Illinois Medical Journal,* July, 1922) says that one often encounters a tendency to regard the x ray findings as a diagnosis; to regard the röntgen laboratory as a place where complete diagnoses are miraculously produced. This is a conception which must be discouraged. The findings of the röntgenologist are often an invaluable adjunct to the clinical findings, but in the final analysis it is the clinician who accepts the responsibility of the diagnosis and prognosis, and it is he who must learn to view the röntgenologists' report in its true light of specialized information.

Tetanus Bacillus as an Intestinal Saprophyte in Man.—Carl Tenbroeck and Johannes H. Bauer (*Journal of Experimental Medicine,* September, 1922) examined stools from seventy-eight male Chinese patients, and from 34.7 per cent. of them obtained organisms which in their morphology and toxin producing properties were tetanus bacilli. The history of the positive cases showed little to bear on the problem. The only method that was found reliable for detecting tetanus bacilli was the culturing of the suspected material, the isolation of tetanuslike organisms and the demonstration that the pure cultures form a spasm producing toxin that is neutralized by tetanus antitoxin. A study of patients who had been in the hospital for some time, and who received practically sterile food, showed that they continued to eliminate tetanus spores in their stools, indicating that the tetanus bacilli were multiplying in the digestive tracts of the patients.

Pathogenesis and Treatment of Exophthalmic Goitre in the Light of Our Present Knowledge

By ALFRED GORDON, M.D.,
Philadelphia.

INTRODUCTION.

The long history of Graves's syndrome indicates the difficulty which clinicians and pathologists experience in their orientation with multiple symptoms and anatomical lesions. Recent researches in this field have not advanced to any extent our knowledge of the subject. A critical review and analysis of the accumulated data, especially from the viewpoint of the pathogenesis of the affection, will perhaps be of some practical value. A description of the fundamental and accessory symptoms which are well known will be omitted. The pathogenesis is the chief concern in this analysis and the treatment will appear as the logical deduction.

PATHOGENESIS.

As long as the understanding of thyroid functions did not reach the stage of our present knowledge, the disease under discussion was generally considered of nervous origin. It was only with observations on myxedema, in which treatment with thyroid extract produced symptoms resembling Graves's syndrome, that a new orientation took place with regard to the origin of exophthalmic goitre.

At present we witness two views; one is that Graves's disease is of nervous origin, and the other attributes the affection largely to a disturbed thyroid function.

FIRST VIEWS.

As to the first, we are in possession of numerous incontestable facts: Barie (1), Mendel (2), Marie et Marinesco (3), and others observed Graves's syndrome in tabes and considered a lesion of the solitary bundle, which is connected with the ninth cranial nerve in the medulla, as the pathological cause of the disease. Joffroy observed exophthalmic goitre in a case of syringomyelia in which he found an angiomatous dilatation of the superior cervical cord and of the posterior portion of the right hemisphere.

The disease was also observed in cases of paresis. Jendrassic published a case of poliomyelencephalitis due to lead poisoning; at a certain moment the bulbar centre became affected and the patient presented the picture of Graves's disease. Parkinson's disease was also observed in association with Graves's disease; myasthenia gravis, encephalitis lethargica, acromegaly, gigantism, and tetany are the other affections of nervous origin.

Some authors are in favor of the cervical sympathetic nerve. They believe that stimulation of the latter produces tachycardia, exophthalmos, dilatation of thyroid arteries, and secondarily, secretory disturbances of the thyroid body. In favor of this contention are the older experiments of Dastre and Morat and the more recent ones of MacCallum and Cornell in 1904. Dastre and Morat long ago had shown that the vascular dilatation brought on by irritation of the cervical sympathetic nerve was manifest when it was directed to the communicating branches of the second, third, and fourth dorsal pairs, and to the segments of the ganglions where these branches terminated; the dilator fibres exist together with the constrictors in the sympathetic nerve. Morat also demonstrated that the inferior cervical ganglion was the principal source of the acceleration of the heart and of vasodilators of the thyroid body. Wilson (4) stimulated the superior cervical ganglion in a dog and found changes in this ganglion as well as in the thyroid. Brian demonstrated long ago an increase in the size of the thyroid after a section of the sympathetic nerve followed by an injection of pilocarpine. For the nervous origin of Graves's disease speaks the influence of emotional factors on its outbreak or on its recurrences. Mosconi (5) calls the thyroid "the gland of emotion." Laignel-Lavastine (6) observed symptoms of the disease occurring intermittently in the course of tabes and coincidentally with gastric crises. The same author, together with Bloch, observed it in a case of pleuritis of the pulmonary apex reaching the cervical sympathetic.

It is a well known fact that the basal metabolism in Graves's disease is greatly increased: in some cases as high as sixty-six per cent. This phenomenon is due to an increased activity of the vegetative func-

Copyright, 1923, by A. R. Elliott Publishing Company.

tions, the result of stimulation of the sympathetic system. It seems, therefore, that some, if not all, of the manifestations of Graves's disease are due to the excitation of the sympathetic system.

ENDOCRINE THEORY.

The second view concerning the pathogenesis of Graves's disease is the endocrine theory.

Möbius (7) was the first to consider hyperthyroidism as the origin of Graves's disease. Experiments and clinical observations following Möbius's announcements have abundantly indicated the probability of his contention. It is sufficient to call attention to Klose's feeding of dogs with thyroid secretion from a case of Graves's disease and the result which was fever, tremor, sweating, tachycardia, and exophthalmos.

CLINICAL DATA.

Clinical experience shows that thyroid extracts employed in various pathological states provoke, when given in large doses, untoward symptoms resembling those of Graves's syndrome. Moreover, in Graves's disease the susceptibility to thyroid extracts is very often great so that the smallest doses of thyroid may provoke accidents. These facts are the strongest arguments in favor of the view of hyperthyroidism. It is also well known that simple goitre is not infrequently the origin of Graves's disease. As an endemic disease in France, in the Alps, Pyrenees, and Jura it is not an easy matter to distinguish simple goitre from exophthalmic goitre. Lesions of the thyroid, such as acute thyroiditis which is frequent in infectious diseases (8) have been the point of departure for Graves's disease.

MIXED TYPES.

On the other hand, competent investigators have shown that not in every case of Graves's disease is there hyperthyroidism. For example, Gley and Cléret in 1911 with intravenous injections of thyroid secretion (from a case of Graves's disease) brought about weakened cardiac beats with decrease of arterial pressure. Even the Goetsch reaction does not always prove its claim: In five of my cases of Graves's disease the reaction was negative in four and positive in only one. Garnier and Bloch have obtained only sixteen positive adrenalin reactions in forty-eight cases (9). Of the same order are the facts of coexistence in the same patients of symptoms of myxedema (which means hypothyroidism) with those of Graves's disease. Similar coexistence of opposed symptom groups has been observed with regard to other endocrinic glands, which shows that the mode of action of endocrinic secretions is not better known in normal than in pathological conditions. The conclusions to which such facts lead are that in Graves's disease the thyroid function is perhaps altered and that excessive thyroid secretion probably plays a certain rôle. That other elements participate, especially the sympathetic, there can be no doubt.

RELATIONSHIP TO GRAVES'S DISEASE.

The difficulty of explaining readily the exclusive part played by a disturbed thyroid gland in the creation or in the accentuation of Graves's syndrome, also the interrelation between various endocrinic glands, led some investigators to determine whether other endocrinic glands besides the thyroid participated in the pathogenesis of the disease under discussion. As to the parathyroids, their function is different from that of the thyroid. While both contain iodine and secrete an acidophilic colloid matter, in the parathyroid these substances exist only in adults and especially in the aged.

The adrenals, it is admitted, produce a thyroid overactivity. Their action may be dependent upon the sympathetic, and vice versa (10). Goetsch, basing his contentions on the view of Falta, Eppinger, and Rudinger, has shown an accentuation of the Graves's symptom group from a hypodermic injection of half a milligram of adrenalin, demonstrating a reciprocal action of thyroid and adrenals by which they reinforce each other in the causation of cardiovascular disturbances and glycosuria (11). Oswald (12) has shown that, after an injection of thyroglobulin, extracted from the thyroid gland, adrenalin increases still more the arterial pressure. The rôle of the pituitary gland is uncertain outside of acromegaly and gigantism. Operation on the pituitary or on the thyroid produced a reciprocal pathological effect. The liver and pancreas have also been observed as having a certain effect on thyroid function.

MIXED DYSFUNCTION.

One writer, Cacika, considers Graves's syndrome due to a disturbed function of the pancreas, hypophysis and adrenals. The pluriglandular pathogenesis has some adherents, but conversely there are also in the literature contradictory data on this particular phase, all showing that their rôle is uncertain and not constant. None of them presents the general characteristics which are evident in the thyroid gland.

In this mass of confusing information one fact nevertheless stands out unaltered, namely, that in Graves's disease hyperthyroidism is present. Moreover, when the activity of the thyroid is checked or diminished by surgery or radiotherapy the Graves's syndrome is considerably benefitted. From the latter viewpoint several propositions may be considered; whether in hyperthyroidism the excessiveness of thyroid secretion alone, or an alteration of this secretion, or the remaining healthy portion of the thyroid gland is to be incriminated in the causation of Graves's syndrome. No definite solution can be offered from the state of our present knowledge.

PRIMARY FACTORS.

The question naturally arises: In view of the existence of several pathogenetic conditions in Graves's disease—the sympathicotonia and hyperthyroidism, which of the two can be considered as the primary factor? The reciprocal influence of both is well known. The largest number of observers consider the action of the thyroid as the primary cause, or the Graves's syndrome as due primarily to the effect of a toxic substance originating in the thyroid and irritating the sympathetic system secondarily. If it is so, why is it that it excites only the cervical sympathetic and why should it not have the same effect upon the other sympathetic nerve which will act on the abdominal aorta, iliac, and femoral arteries? Besides, there are cases in which there is enormous exophthalmia associated with an insignificant thyroid enlargement and moderate tachycardia, and vice versa. There are also cases without struma. There are cases with unilateral symptoms. How is it possible that a general toxemia by abnormal thyroid secretion can produce conditions like these?

There are also cases in which genital affections determine exophthalmic goitre, cases in which a floating kidney produces the same condition which subsequently disappears when a suitable abdominal belt is put on to support the kidney. Enteroptosis and gastroptosis have been followed by Graves's syndrome. The same was observed in nasal polyps, and hypertrophy of turbinated bones. Tillaux performed a successful thyroidectomy and four years later exophthalmic goitre developed. On the other hand, Filehne injuring a certain spot in the medulla in rabbits produced the symptoms of Graves's disease. At autopsy were found hemorrhage of the fourth ventricle, dilatation of bloodvessels and atrophy of funiculus solitarium.

THE NERVOUS SYSTEM.

Mention was made above of organic diseases of the nervous system in which Graves's syndrome eventually developed. All these facts tend to prove that in Graves's syndrome all the phenomena are the result of a permanent irritation of the vasodilator nerves situated in the cervical sympathetic nerve, and as the vasodilators of the head and heart have their deep origin in the medulla, it is there that we must look for the explanation. The sympathetic nerve sends its nervous filaments to the bottom of the orbit, the thyroid gland, and the cardiac plexus. With a permanent irritation of the vasodilators coming from its centre there is a constant afflux of a considerable amount of blood to the thyroid and retrobulbar vessels. It seems, therefore, that the sympathetic nerve is the immediate cause of Graves's syndrome.

Accepting this contention as correct, one should not lose sight of the fact that Graves's syndrome may be brought into evidence or become accentuated the more readily as the more sensitive is the sympathetic system. Excitation of the latter may result from many conditions, among which an important place is given to endocrinic products, the hormones or metabolites (Gaskell) which the English authors call "chemical messengers." These products determine a great variety of reactions which may become associated or destroyed according to the state of the secretory organs. The presence of apparently contradictory manifestations in the course of Graves's disease is due precisely to the activity of the various hormones and by no means invalidates the condition which seems to be the principal one in the mechanism of Graves's syndrome. Their presence depends upon whether they stimulate the sympathetic or the vagotonic portion of the vegetative nervous system in any given case of the Graves's symptom group. Moreover, the excitability of these systems is probably not uniform in all their portions, which explains also the diversity of their reactions. A brief description of these two systems seems to be warranted at this juncture.

SYMPATHETIC SYSTEM.

The sympathetic system originates in the spinal cord from the second thoracic to the second lumbar segment. It controls vasomotricity, pilomotricity, the smooth fibres of the dilator of the iris, the sphincters of the digestive and urinary apparatus, the sudoral secretion, and the chromaffin apparatus. A functional disturbance of this system will produce precisely the symptoms observed in Graves's disease; they are consequently due to sympathicotonia. The symptoms are as follows: cardiovascular disorder, viz., tachycardia with slight hypertension; ocular phenomena (tendency to exophthalmia, mydriasis); nervous phenomena, such as sensations of heat, insomnia, tremor, disturbed oculocardiac reflex; decreased salivary secretion, positive Goetsch reaction, increased basal metabolism, provoked hyperglycemia.

VAGOTONIC SYSTEM.

The vagotonic system consists of two portions; a, cranial, which originates in the area of the cerebral peduncles and medulla, and transmits its influence through some of the cranial nerves, and b, a pelvic portion which originates in the lower portion of the spinal cord and is distributed in the lower portion of the abdomen. Its symptoms are bradycardia, which can be modified by atropine, which accelerates the heart; amyl nitrite and ocular compression, which slow up the heart beat; dyspnea; gastralgia; increased peristalsis; constipation; salivation; pupillary contraction. Pilocarpine produces these symptoms. Atropine, on the contrary, depresses the vagus and amyl nitrite and adrenalin excite the sympathetic.

In normal health both opposing systems are constantly at work, they are uninterruptedly under the influence of various stimuli and according to the predominance of one or of the other, the resultant will give corresponding predominating phenomena. This is the reason for the diversity of manifestations in pathological states—the contradictory conditions met with are apparent only, depending upon the character of the excitant and the organ involved.

The present methods of treatment of Graves's syndrome are either medical or surgical.

MEDICAL TREATMENT.

Diet and hygiene.—First of all, dietetic and hygienic measures are of considerable importance. Excitants of the nervous system must be prohibited, namely, alcohol, tea, and coffee. Food producing the least amount of toxic material, such as milk, is the most appropriate. Physical exertion must be avoided and a prolonged rest in bed is advisable. Emotional factors are to be removed. Coitus must be reduced to a minimum. Pregnancy should be avoided. Country life is advisable. High altitudes must be avoided. Hydrotherapy is beneficial but extreme temperatures of the water is contraindicated.

Electricity.—Electricity has been used. Erb advises galvanism. The positive electrode is to be placed on the neck between the fifth and the seventh cervical vertebræ, the negative on the goitre. Faradism is used exclusively by Vigouroux. The modern method is galvanofaradism; the voltage current of ten to twenty milliamperes is used first, the positive pole on the neck, the negative on the thyroid. This is followed by a moderate faradic current during ten or fifteen minutes. The positive electrode is placed in the third intercostal space near the sternum on the left, and the negative on the neck. Finally, a very slight current is applied to the eyeglobes, the positive pole to the orbicularis, the negative to the neck. Claims have been made as to the amelioration of the symptoms, especially of the cardiac and of the general nervousness, but I have never observed improvement from electricity.

Opotherapy.—This is another form of treatment. Antithyroid medication was initiated by Gilbert Ballet in 1895. In conjunction with Enriquez (13) he administered the serum of thyroidectomized animals. Their results, as well as those of others, have been uncertain. Whether in Graves's disease one deals with thyroid insufficiency or with an abnormal thyroid secretion, according to some writers thyroid extracts seemed to be indicated. Here again the results of such a treatment varied. In all events, it is advisable to commence the drug with minute doses. It should be altogether avoided in pulmonary, renal, and cardiac organic affections as well as in glycosuria.

Thymus gives contradictory therapeutic results. Pituitary body is sometimes effectual by producing a vasoconstriction of the thyroid bloodvessels leading to a decrease of tremor. Adrenalin, as is well known, increases sympathicotonia. However, Shapiro and Marine (14) obtained very satisfactory results from adrenalin. Quinine being a vasoconstrictor is sometimes very efficacious. It may be associated with ergot, and it may be given in its newer form, namely quinidine sulphate. Sedatives and antispasmodics are advisable, such as bromides, valerian, belladonna, and coaltar products. Although iodine in simple goitre sometimes aggravates the condition, in Graves's disease it gives satisfactory results. It should, however, be given in very small doses at first. Loewy and Zandek (15) give iodide of potash in extremely small doses, viz., .025 to .12 gr. a day discontinuing it as soon as there is a decrease in weight. The maximum dose is twenty drops three times a day of five per cent. solution. The improvement is accompanied by a reduction in the generally increased metabolism. Injections of iodoform and tincture of iodine into the thyroid body have been advised, but they are connected with risk as to suppurations and hemorrhages.

SURGICAL TREATMENT.

Ligation of the thyroid arteries was advised first by Mikulicz, as a preliminary operation for an eventual extirpation of the gland. Kocher ligates first one artery, later the other artery, and finally he excises the diseased lobe.

Thyroidectomy was first advised by Tillaux in 1880, but total extirpation leads to cachexia and myxedema. At this time only partial thyroidectomy is performed and in several séances (Kocher). The parathyroids must be preserved.

Finally, resection of the cervical sympathetic is one of the operations strongly advised by some clinicians. In view of the ever present sympathicotonia in Graves's syndrome one would expect amelioration of symptoms from such a procedure. However, experience has shown that in some cases the operation was followed by permanent trophic disturbances. Herbert's statistics (16) show a mortality of nine out of forty-one cases. Moreover, since the sympathetic system consists of several centres a partial resection will not always answer the purpose.

Leriche (17) advises avulsion of some fibres of the sympathetic, particularly those surrounding the internal carotid. Great difficulties, however, are encountered in finding precisely those nerve fibres which could be incriminated in any given case. On the other hand, the experience of Jonnesco, Faure, and others in removal of the cervical portion of the sympathetic nerve is quite encouraging. It seems that the really rational operation will be the total resection of three cervical ganglions and of the cord uniting them, because the superior ganglion is the source of the ocular filaments and the inferior ganglion is the source of the accelerators of the heart and of the vasodilators of the thyroid.

In view of the fact that partial thyroidectomy combined with a ligature of the thyroid arteries is the operation of choice by some surgeons in certain countries, it is well to bear in mind the contraindications for such an operation. They are cachexia or grave visceral disturbances, marked tachycardia, psychic manifestations, and finally diabetes. A preparatory phase for an amelioration of these symptoms should always precede operative procedures of any kind.

The results of surgical intervention are various—partial or complete successes may be met with as well as failures by all methods.

RADIOTHERAPY.

This is another method of treatment. Weekly applications of x rays to the lateral and median lobes are sometimes useful. Béclère (18) advises continuing applications until the pulse is 80 in the morning hours and until there is increase in weight. The functional disturbances usually improve rapidly, but the thyroid and the exophthalmos are the last to improve. The results are variable. Experiments on rabbits have shown destruction of thyroid elements from x ray applications. Concerning radium, Abbe obtained very satisfactory results in 1905, although the experience of others is somewhat contradictory, and at best the results are not superior to those from x ray applications.

In discussing the treatment of Graves's disease one should always consider the slight and the grave forms. In the former, medical treatment alone may be sufficient. In the grave forms a trial of medications together with dietetic and hygienic rules, hydrotherapy, electrotherapy, and radiotherapy should always be considered and administered, and only in case of absolute failure is surgical intervention in several séances to be undertaken. It is well to bear in mind in all cases the possibility of a luetic etiological factor. A trial with specific remedies is always advisable.

The Physiological and Pathological Importance of the Thyroid Secretion

By H. STANLEY-JONES, M.B. (Lond.),
Southampton, England.

Among the recognized glands of internal secretion the thyroid must, as far as our present knowledge extends, hold premier place. Its influence is evident at all ages of life, and a close study of its activities will repay us well, in whatever branch of medicine we may be interested.

In infancy, in childhood, in youth, middle and old age, we can discover evidence of its function and a study of its influences at each of these periods of life is of great importance to every clinician. Our investigation will not be complete, however, for we ought to extend our study further back into the life history of the individual. We must examine the part played by the thyroid on the growing fetus, the unimpregnated ovum, and finally on the ovaries and uterus of the mother, as well as the spermatozoa of the male.

To begin therefore with the union of ovum with the spermatozoa, where does the thyroid come in here? To answer the query one must introduce a theory of heredity which is not irrational, and which presupposes that in the fecundated ovum are represented all the hormones which the individual will eventually possess. As each impregnated ovum is composed of male and female elements, its hormonic constitution will be derived from both parents. A thyroid deficiency in the female would therefore be reflected in the ovum, and the same applies where the male is concerned, the defect being adjusted where deficiency in one parent is counteracted by excess in the other, or accentuated where both are deficient.

The future individual therefore starts his existence as a cell reflecting the combined hormonic constitution of his parents, and there will be predominating characteristics in the growing ovum and the mature individual in accordance with the predominating hormonic influences brought to bear by either parent. The nutrition of the growing fetus, however, depends on the mother, and here the thyroid of the mother is of the utmost importance. The pregnant mother requires an ample supply of thyroid hormone for the physiological changes which are involved in the development of the fetus. The thyroid hormone is essential for normal growth, and the physiological enlargement of this gland during pregnancy gives evidence of this need.

The presence of a living fetus in the uterus appears to act as a stimulus to the thyroid. It is thus we see young women who, before marriage, were anemic and generally below par, benefit so much by this increased thyroid activity associated with pregnancy. This thyroid stimulation by the fetus would appear to be nature's method of securing that necessary amount of hormone upon which the growth of that fetus so largely depends. The increased thyroid secretion, however, benefits the whole body, as shown by the improvement in health generally.

The fetus may itself exhaust all the available supply of hormone, that is to say, the maternal thyroid may be unable to respond sufficiently to the increased demands, and while the fetus is adequately supplied the maternal tissues may have a deficiency.

We then encounter some of those distressing disturbances associated with pregnancy especially in the early months, such as nausea and vomiting, pyrosis, heartburn and flatulence, salivation and constipation. In later months eclampsia may develop as a result of this thyroid deficiency.

If the amount of hormone is so small that the fetus itself has insufficient then the fetus develops badly and there will be a liability to abortion and premature labor, and possibly malformation of the child. A liberal supply of thyroid hormone is accordingly most essential during pregnancy. The fetus requires it for proper growth and development, the uterus requires it for its own nutrition and expansion and the maternal tissues have need of it to meet the increased demands on them for metabolic purposes. While thyroid deficiency is associated with poor development of the fetus, it is also one, at any rate, of the causes of abnormally sized children. Babies eight pounds and upwards reflect some thyroid defect in the mother. Large children are usually the product of protracted gestation and this again is an indication of indifferent thyroid action. The women, also, who, in spite of the size of the fetus experience protracted and difficult labors, are probably of the same type.

The thyroid has been called the female gland—that is to say it plays a relatively more important part in the physiology of the female than that of the male. That being so it gives us an explanation of why male children at birth are, on the average, larger than the female. The females have had a more generous endowment of thyroid hormone and it naturally follows from this that the female fetus develops in size more normally than the male, and is in most respects a more healthy infant. It is known that male children are more difficult to rear than females.

After birth of the child the problem of the thyroid secretion is just as important as it was before birth, for the infant requires sufficient hormone for physiological growth. Before birth it received its hormone through the maternal blood. After birth it has to obtain it from the mother's milk. Here the importance of the maternal milk comes in. Mother's milk deficient in thyroid hormone means an ill-thriving child. It is probably one at least, of the causes of the mother's milk disagreeing with the child. An infant up to nine months old depends on outside sources for its thyroid hormone. It cannot manufacture it for itself, for, as will be explained later, the thyroid gland depends on certain intestinal bacteria for the elaboration of its secretion, and suitable flora are not present in the child's intestine until it is nine months or more. After this age it can manufacture its own secretion.

The failure of the mother's milk entirely, or its inability to satisfy the needs of the suckling child invariably leads to the employment of cow's milk, fresh or dried. This procedure is often attended by difficulties owing to unsuitability, from varying causes, of fresh cow's milk to the infant's digestion. Milk from certain cows may prove suitable, from other cows it may disagree. Hence the use of socalled nursery milk from selected cows. The problem of the thyroid comes in here again. If the child is unable to secure its thyroid hormone from its mother's milk, it must do so from the substitute, namely, cow's milk. Cow's milk, however, may, and indeed often does, vary in its thyroid hormone content, and children will thrive on this milk, apart from gross abnormalities in the chief constituents, in proportion to the content of the hormone present, or, what amounts to the same thing, its relative iodine content.

Dr. Ewan Waller (1), of Birmingham, a year or so ago, investigating the prevalence of goitre in cows and incidentally in children, in British Columbia, found that the latter were less prone to goitre in the summer months and more liable in the winter. During the summer months cow's milk showed a high content of iodine, but during the winter there was a deficiency.

The question of infant feeding, therefore, has an importance in regard to the iodine or thyroid hormone content of either the mother's milk or its substitute, and this factor, particularly as it affects cow's milk, has been very little emphasized, for it raises the question as to whether the dietetic value of cow's milk could not be improved when shown unsuitable, by the administration of iodine in some form to milking cows.

After nine months old the child is normally weaned. From this onward the child begins to manufacture its own thyroid secretion. Failure to do so leads to a large number of pathological conditions and disturbances of growth.

There are four more or less cardinal signs of defective secretion up to the age of two years—1, adiposity; 2, delayed walking; 3, delayed talking; 4, late dentition. As the child gets older, backward growth and mental retardation become noticeable. This is particularly observable in the various types of cretins. We also find it in such conditions as Infantile myxedema and congenital syphilis.

Tonsils and adenoids and enuresis are products of a mild degree of thyroid deficiency. Children who are poor feeders without apparent cause are often of the same type. Some other minor indications of this deficiency in children are drowsiness, constipation, itching of the skin as a result of sluggish liver, lordosis, undescended testicle, umbilical hernia, and knock knee. Apparently we must add to this list hydrocephalus, for a case of this disease was reported in the *Lancet* of July 22nd last as having been cured by thyroid extract.

The influence of the thyroid on growth and the bodily activities continues up to the period of puberty. With the approach of sexual maturity, and during the whole of sexual life, the thyroid comes more and more into the limelight, and this is especially so in the female, so much so that the thyroid is not without justification sometimes called the female gland. For perfect physiological health the female, even more than the male, requires a good thyroid. If during her period of growth the girl has experienced a poorly secreting thyroid, her sexual organs are likely to be badly developed. She may have a small infantile uterus, inactive ovaries, and her menstruation probably defective or lacking, and she may have dysmenorrhea. The bony pelvis may also be abnormal. The thyroid at puberty acts as a general stimulant to the physiological activities of the ovaries and testicles.

Deficiency becomes evident in such conditions as chlorosis, amenorrhea, and poor circulation. Badly acting ovaries as a result of lack of thyroid stimulation account for many cases of obesity in young women.

The importance of the thyroid to the pregnant woman has already been discussed; indeed during the whole of the reproductive life of the woman a good supply of thyroid hormone is necessary for efficient child bearing. The more children are born the more is it requisite that the thyroid should not fail, for frequent pregnancies put a strain on the capacity of the gland.

At the menopause, when sexual life is becoming dormant, we find the thyroid developing into a condition of instability. The ovarian function lessens, and if the changes in the gland secretion, both as regards the thyroid and ovaries, are gradual, then the climacteric may be passed through without much distress, but where the change of life is more sudden, we find the thyroid unable to accommodate itself to the new conditions, then we have distressing symptoms due to alternations of thyroid activity and inactivity.

After forty years of age or so both in the male and female we note a period of declining physiological activity on the part of the thyroid. For a comfortable and enjoyable old age, both sexes need a continuation of physiological activity on the part of this gland. Deficiency at this period of life involves the production of innumerable conditions of ill health which could be much relieved were the underlying cause appreciated and its ill effects anticipated. Probably this physiological decline in middle and old age is more noticeable in men than in woman. Normal woman starts life with a more generous endowment of thyroid than man. Her thyroid, therefore, lasts longer, the man's thyroid wears out quicker.

Men are more liable to the degenerative changes which are associated with thyroid deficiency, such as aneurysm, arteriosclerosis, high blood pressure, granular kidney and the sequelæ, cerebral hemorrhage.

This is partly accounted for by the greater physical activity of men and to their more generous indulgence in food, alcohol and tobacco. They absorb more toxic products than the thyroid is able to deal with. They put a greater strain on the thyroid than do women.

This brief survey, necessarily incomplete, is sufficient indication of the physiological importance of the thyroid hormone at all periods of life. We have now to consider what is the chemical constitution of this secretion, how it acts and in what way is it associated with pathological conditions in the body.

The active principle of the thyroid secretion is known as thyroxin, the name given to it by Kendall who first isolated it. Chemically it is called thyrooxy-indol and the essential feature of the formula is the presence of an indol group with three iodine atoms. Thyroxin is an iodine compound of indol which is a decomposition product of tryptophan, a constituent of the protein molecule. Indol is split off by the intestinal bacteria, particularly Bacillus coli, and this exchange explains how an infant up to nine months fails to manufacture its thyroid secretion—for its bowel contains hardly any Bacillus coli, and it shows how we depend on these bacteria for the elaboration of an important hormone.

It is to the iodine content of thyroxin that we look when considering the action of this substance on the cells of the body, for it contains sixty-five per cent. of iodine and the test of the value of any thyroid extract lies in its iodine content.

The essential action of thyroid hormone is that of an activator or accelerator. It stimulates all those chemical changes which constitute the normal physiological processes occurring in the cell. Cell activity and oxidation are increased under this stimulus.

When this stimulus is within physiological limits then the changes going on within the cell fulfill the normal physiological requirements of that cell. That is to say the metabolism of the cell constitutes a normal balance between anabolism and catabolism. Herein lies the great importance of the thyroid hormone—its function of stimulating the normal metabolic changes in the cell, and it is when these changes in the cell are deranged that we encounter the varied pathological conditions of which we get clinical evidence every day. These pathological conditions may arise from over stimulation of the chemical changes in the cell or from deficient stimulation brought about by thyroid excess or thyroid failure.

Thyroid excess produces catabolic changes in the cell—the activity of the cell is greatly increased, oxidation becomes excessive, decomposition of proteids proceeds further than normal, calcium, phosphorus and nitrogen are excreted in undue proportions. The result is loss of weight, and raised temperature (owing to excessive oxidation). On the other hand, where the stimulus is lacking, a condition of anabolism is produced, changes in the cell are retarded, protein material is not sufficiently broken down, and the cell accumulates waste material, which it should normally get rid of.

We see thyroid excess well illustrated, clinically, in Graves's disease and thyroid failure in myxedema. Between these two extremes we have a vast number of conditions which have as their basic defect more or less excess, or failure of thyroid activity.

The main clinical manifestations of excess of thyroid are—raised temperature, increased pulse rate, moist skin, general restlessness and excitability, loss of flesh, tendency to diarrhea. It is important to remember, however, that these clinical manifestations are not due merely to the thyroid excess. There is a fairly wide range of thyroid action within the limits of which the clinical signs of excess are not observable. These limits vary according to age and also according to requirements of the body at any particular moment. There is a physiological elasticity in the functioning of the thyroid. Under certain conditions, however, thyroid excess becomes pathological, that is to say it produces many or all of the clinical signs just mentioned. This is very well demonstrated by the experiment of Kendall and quoted by McCarrison (2) in his book on the thyroid gland, who showed that injection of thyroid hormone into a healthy animal's blood does not affect the animal, but when combined with amino acids it produces marked toxic effects. In other words, if you have an active thyroid and a toxemia combined, then you expect severe constitutional reactions.

It is possible to make the further deduction from this experiment, that a toxemia circulating in blood with a poor supply of thyroid hormone will give much less constitutional disturbance than if the thyroid hormone were present in abundance.

A German writer—Fleckseder (3)—recently pointed out that patients with active thyroids, such as those with Graves's disease, are poor subjects for typhoid. Those with normal or deficient thyroid run a mild course. What applies to typhoid undoubtedly applies to acute febrile conditions generally. Fever is a condition of increased metabolism, and there are, according to Aub (4), two glands particularly responsible for the production of fever—the adrenals and the thyroid, and of these the thyroid is by far the more important.

It follows from this that acute febrile diseases will be more common at that period of life when the thyroid is most active. A survey of the age incidence of various acute febrile conditions confirms this. Rheumatic fever is rare after forty; typhoid is commonest from ten to twenty-five years of age; acute phthisis is typically a disease of youth; pneumonia much less frequent after middle life, and many other acute diseases might be quoted in illustration of a similar age incidence. Acute rheumatism is a good example of thyroid excess associated with toxemia, and the heart lesions in this infection are similar to those produced by thyroid excess. Hashimoto (5) administered continuous toxic doses of thyroid extract to rats, and he found that he produced an enlargement of the heart and myocardial lesions of a chronic nonsuppurative nature, practically identical with those found in the myocardium of human subjects suffering from acute articular rheumatism.

Acute phthisis gives evidence clinically of thyroid excess. Its virulence is greatest during puberty and active sexual life—a period of great physiological thyroid activity. If a phthisical patient can be kept alive until after forty then his chances of recovery are great, for he enters upon a period of declining thyroid activity.

There are two diseases seldom associated with thyroid excess but which have a definite connection with it, acute syphilis and acute gonorrhea. Both these diseases are worse in patients with active thyroids and mild in those with deficient thyroids.

Chronic or tertiary syphilis and chronic gonorrhea on the other hand exhibit signs of thyroid deficiency. While salvarsan in the treatment of syphilis is directed to the object of killing the spirochetes, it also has the effect of depressing the thyroid, and if you depress the thyroid you produce a condition unfavorable to the multiplication of the spirochetes in the blood.

If in an untreated case of primary or of secondary syphilis you administer a sulphur preparation such as contramine, or iodide of potassium, both of which stimulate the thyroid, then the disease will become worse, for you are encouraging conditions favorable to the growth of the spirochete.

In tertiary syphilis we find spirochetes disappearing from the circulation and reduced in number embedding themselves in tissues away from the main blood stream and surrounded by fibrous tissue. In this (tertiary) stage of the disease the thyroid is depressed and the spirochete has less favorable conditions for development. It is also in this stage that thyroid stimulants, such as iodide of potassium and sulphur, are so valuable in counteracting the effects of the thyroid deficiency.

Acute gonorrhea equally illustrates the influence of the thyroid on the severity of the symptoms. If this disease is treated merely by irrigations, the importance of the thyroid will be overlooked. Control your thyroid and you will break the back of your disease. Syphilis and gonorrhea are diseases which, in my experience, respond much more effectively to treatment based on recognition of their relationship to thyroidal activity than to the ordinary routine methods.

To understand fully the relationship of the thyroid to acute infections one important fact must be recorded. In thyroid excess there is abnormal loss of calcium from the body, and the importance of this lies in the connection between calcium and immunity. Blood deprived of its calcium loses its immunizing power. If sodium citrate is added to blood, complement will be found much reduced and the leucocytes lose their phagocytic power. Sodium citrate acts by neutralizing calcium. In thyroid excess therefore there is danger of failure of immunity for the reason that calcium is likely to be diminished in the blood owing to excessive excretion from the body.

Now Graves's disease is a typical example of thyroid excess and it is well known how likely acute infections may develop in these patients. They do badly if tuberculosis or typhoid, pneumonia or venereal disease, and indeed any acute infection develops.

Thyroid excess has great significance in regard to septic infections generally.. Septicemia, for instance, becomes of much graver import, when the infecting agent is associated with an actively secreting thyroid.

Acute appendicitis has a more rapid course when associated with thyroid excess. When we come to the nervous system we find the thyroid exerting its influence here also. People with good thyroids are active, bright, cheerful, restless; given a period of hyperactivity of their thyroid they may show signs of over excitability and even mania may develop, Their whole nervous system shows the influence of the overstimulating action of the thyroid hormone on the nerve cells. Graves's disease exhibits the nervous features very well in a mild form. The nervous system, in turn, has a definite influence on the thyroid, and it is important to recognize this influence, for excitements, emotions of all kinds, have a stimulating effect on the activity of the gland. Quietness and rest therefore are physiologically correct treatment in dealing with hyperthyroidism, and is what we universally adopt in all acute infections. To allow excitement makes the disease worse by adding still further stimulation of the thyroid. I have quite frequently seen this very prettily demonstrated in cases of subsiding gonorrhea where the discharge has ceased. Any severe excitement, sexual or alcoholic, or an emotional disturbance such as a bereavement, promptly brings the discharge back again. The importance of rest is particularly evident after parturition. Now during normal pregnancy there is a physiological hyperthyroidism. It is not an excess for the mother and child have use for it. After parturition there is likely to be for a few days an excess, and it is one of the causes of excessive loss of blood where there is no obvious local cause in the uterus to account for it. Complete rest therefore, to allow the thyroid to quiet down, is indicated after labor and is of course universally practised.

There is another feature of thyroid excess which ought to be dealt with. It is that associated with hyperthyroidism; there is an increased sugar content in the blood. This has a particular interest, as it directly associates the thyroid with acute diabetes. The thyroid hormone and the internal secretion of the pancreas are antagonistic. Elevate one and you depress the other. If therefore you get a faulty functioning pancreas as a result of some local infection or otherwise, associated with an overactive thyroid, then the blood sugar is so greatly increased that sugar appears in the urine, and the clinical signs of acute diabetes reveal themselves.

This explains why diabetes is so fatal in the young for it is a period of life during which the thyroid is most active.

Acute diabetes well illustrates the value of rest in cases of hyperthyroidism. If you allow any emotional disturbance to be brought to bear in this disease, then sugar will return or be increased on account of the added thyroid stimulation. Sufficient indication of the importance of appreciating the part played by the thyroid in acute infections has been given. These indications point to one thing: that if you can control your thyroid you can influence the course of your disease to a material extent. Your disease is acute not merely because your infection is acute, but because your infection and your thyroid have combined to make it so.

If we now turn to the opposite condition, thyroid deficiency, we have a state in which the cell lacks the stimulation of the thyroid hormone. We then have stagnation as manifested so typically in myxedema. The whole body is in a condition of sluggishness, mental and physical. The symptoms of myxedema are well known and need not be dilated on. The clinical signs of the minor degrees of thyroid deficiency are of more practical interest because they are to be met with every day. A great number of these manifestations have already been recorded in discussing the importance of the thyroid at different periods of life.

The essential feature of hypothyroidism is the excess of anabolism over catabolism. The body fires, as it were, burn too sluggishly and leave too much clinker. The immediate result is accumulation, but the ultimate result is degeneration. For a cell to be healthy it must be continually renewing itself. The hypothyroid cell does not renew itself sufficiently often. One of the clinical manifestations of hypothyroidism is a persistently low or subnormal temperature. Slow pulse rate is another feature, and cold extremities a third. When we find such clinical signs as these in a patient we administer thyroid extract and we find the symptoms clear up more or less effectively. The thyroid has stimulated the metabolism of the cells, enabled the cell to burn up the accumulated waste products and increased the activity of the cell generally. Temperature and pulse become normal and extremities become warm.

Now thyroid deficiency is generally associated with toxemia of some sort, and by giving thyroid extract to these patients one finds that the toxemia very frequently is overcome. For this reason thyroid hormone is commonly called an antitoxic agent. This is a perfectly justifiable description, for what the thyroid hormone can do for the normal proteids of the body in splitting them up and making them more suitable for the needs of the cell, so also can it split up the foreign proteids or proteid toxins of bacteria introduced from outside. Everyone, however, who has administered thyroid extract has come across cases where they have had to abandon the administration on account of tachycardia, excitability, and perhaps rise of temperature. The explanation of this is clear; you have given more thyroid than the body at the moment can use. The excess combined with the toxic elements to produce constitutional disturbance. It brings us back again to the same problem discussed earlier of an acute infection being due to a combination of toxin and thyroid. It also gives us the hint that when we treat thyroid deficiency by means of thyroid extract we must not forget to remove, as far as we can, any underlying toxemia, which has helped to depress the thyroid. Probably the most common origin of toxic absorption is in the mouth, or intestinal tract. Teeth, tonsils, and nasal passages are obvious delinquents and when the infection can be traced to the bowel the combination of thyroid extract with calomel, grey powder, or any of the numerous intestinal antiseptics, has much greater effect than merely giving the extract alone.

Vaccines, where the organism causing the trouble can be isolated, are frequently useful.

To search for the infecting agent is just as important in thyroid excess as in thyroid failure and indeed in excess and in failure the removal of the toxic influences may and often does remove the clinical evidences of both.

The Probable Normal and Pathological Physiology of the Thyroid*

By JOHN ROGERS, M.D.,
New York.

I had thought at first of entitling this article The Surgical Neuroses of the Thyroid, surgical implying that the thyroid was an organ which, by viscously overacting, caused trouble and should be extirpated. The neuroses would apply to abnormalities of function of one or more parts of the nervous system for which there were no demonstrable nerve lesions. Neuroses are due to deficiencies or defects in nervous biochemistry. In studying failures and defects in thyroid activity we find striking analogies to vitamine deficiency.

The hyperthyroid neuroses form the chief subject of interest and as this condition is made worse by feeding thyroid we know that the digested thyroid is the same as the normal thyroid product and therefore that the organ should be removed. The symptoms of exophthalmic goitre point to an increase in functional activity of the autonomic or vagus part of the involuntary nervous system. The sympathetic portion of this system is quiescent and clinically shows no sign of being stimulated by the thyroid.

Fifteen years ago I read before a medical society in Philadelphia, a paper on the serum treatment of hyperthyroidism. A man in our laboratory had damaged the kidneys of rabbits by injecting into them an antiserum made from the kidney nucleoproteins. I suggested a similar experiment for the thyroid and tried it out on three patients. The first was a case of acute toxic hyperthyroidism of three or four days' duration, which had appeared without warning. Three doses of serum acted like diphtheria antitoxin. In the second case the patient was cured in one month by two doses, and the third patient also recovered. After experimenting with a large number of cases, however, the treatment was found to be very uncertain and I concluded that surgery was safer and more satisfactory.

Tracing the history of hyperthyroid patients, I find that they begin as a primary failure or hypothyroidism, the hyperthyroid condition developing later. The nervous person has been subjected to a strain too great for the involuntary nerves to resist. There is first a fatigue failure of the autonomic manifested by lack of drive or hypothyroidism; then an added failure of the sympathetic or check mechanism. After the development of hyperthyroidism all the symptoms including exophthalmus are increased by conditions requiring expenditures of energy—nutritional, mental, nervous or physical—but further back in the history there has generally been a stage of headache, constipation, or anorexia. These symptoms with goitre and fatigue indicate hypothyroidism. Thus the majority of these cases begin as hypothyroidism and later the failure of nutrition becomes hyperthyroid, passing through a stage where the two conditions (hypothyroid and hyperthyroid) are mixed.

---

*Abstract of a lecture delivered before the Philadelphia County Medical Society, January 11, 1922.

I have tested in the laboratory all possible thyroid extracts on animals. With the noncoagulable (alcoholic extract or a hydrolyzed aqueous extract, thyroid residue) I made the following observations on dogs which I injected: 1, vasodilatation; 2, pulse unaffected, in some instances slow; 3, in Pavloff stomach gastric flow was increased five to twenty fold in fifteen minutes; 4, flow of hydrochloric acid stimulated; 5, pancreatic secretion increased ten fold; 6, gastric and intestinal peristalsis stimulated; 7, contraction of longitudinal muscle and uterine muscle stimulated.

I also found that when the vagus was cut above the diaphragm or after the injection of atropine, that is, in conditions where the end plates of the vagus had been destroyed, there was no result after an injection of thyroid.

In like manner, as the thyroid acts so strongly on the vagus, so the sympathetic responds to the adrenal, and in experiments with nucleoprotein and adrenal residue (that part of an aqueous extract which remains after the removal of all coagulable materials) extracts of these glands I found that there was a checking of gastric and pancreatic secretions and a constriction of the circular fibres of the intestine. Adrenalin differs from the extract of whole gland in that it has little or no effect on stomach or pancreas. Since the adrenal extract produces inhibition of the whole gastrointestinal tract, I tried it on the thyroid. An alcoholic or residue extract of the whole adrenal gland given hypodermically to dogs proved violently toxic (thyroid can be given with impunity). When given adrenal nucleoprotein by mouth, however, there was a fifty per cent. gain in iodine in six weeks, while with the hydrolyzed aqueous extract (adrenal residue) the gain was seventy-five to 150 per cent. Analogous to its action upon the stomach and pancreas the adrenals thus seem to inhibit the thyroid, probably through its sympathetic nerve supply. Pure adrenalin, on the other hand, shows no effect upon the thyroid iodine content.

From both experiments and clinical observations it may be stated that all hyperthyroid tendencies are due to overaction of the ends of the autonomic or vagus system, as seen, for example, in the overaction of the gastrointestinal tract and flushing of the skin (vasodilatation). It is therefore reasonable to say that the thyroid acts through the autonomic or vagus and the adrenal through the sympathetic system. From electrical and chemical tests the general functions of the two systems seem to be contrasting. The vagus system activates or drives and the sympathetic system inhibits or checks. Apparently, the thyroid acts by stimulation of the vagus, and so participates in the drive; the adrenal product acts through and upon the sympathetic and so checks. There is no clinical evidence to inform us about hypoadrenalism and hyperadrenalism, but in hypothyroidism and hyperthyroidism the evidence is plain. In the symptomatology of thyroid disorders it is well to think of drive; if there is drive plus goitre, there is hyperthyroidism; if there is lack of drive plus goitre, there is hypothyroidism, in extreme cases myxedema. There are mixed cases in a stage between hypothyroidism and hyperthyroidism and in these the question of operative or medical treatment comes up. This is determined by summing up the amount or lack of drive. If the drive is excessive, e. g., if the patients are too hungry and the bowels move too freely, the condition is hyperthyroid and if it persists surgery is required.

Clinically, there are three points to be considered: 1, the amount of hyperplasia; 2, the distribution of hyperplasia; 3, the location of hyperplasia. There are three types of cases: 1, The typical hyperthyroidism with a symmetrical goitre characterized by irregularly shaped alveoli which may break up to form multiple small alveoli scattered diffusely through the whole gland; 2, a less common type in which one lobe is enlarged and contains hyperplastic alveoli while the other lobe is more or less normal; 3, the toxic adenomata single or multiple. In the last group the single toxic adenoma apparently begins as a hypothyroid condition. The gland becomes congested and there is hemorrhage, followed by a hyperplastic process, multiplication of alveoli and often cyst formation. If the toxic adenomata are cut out and the normal tissue left the patient quiets down to a normal or hypothyroid condition. In the second group, with one lobe enlarged, excision may bring about a cure; the patient may subsequently pass into the hypothyroid stage, becoming weak, tired, pale, with no appetite and no energy. Fatigue may lead to another advance or relapse into hyperthyroidism with the hyperplasia scattered diffusely throughout the entire gland. In the first set it depends upon how many toxic alveoli are left whether the patients recover. In these cases operation is much more hazardous than in the other two types. In such cases it is my practice to ligate all four thyroid arteries in two stages and in a series of five hundred cases I have had a mortality of two per cent. The sum total of my results shows eighty-five per cent. cures. The patients are always treated medicinally after operation, my theory in this procedure is that, as the impulses forcing overaction come through the blood or nerves or both and as the chief influence is through the blood, cutting off the blood supply will quiet the activity of the gland and this with medicinal treatment effects a cure. I urge the use of this method in view of the probable development of hyperthyroidism from the hypothyroid condition and also because there is no way of determining how much of the hyperplastic gland can be removed surgically without permanently losing drive or failing to cure the hyperthyroidism. As to surgical technic, ligation of the superior thyroids causes pain for two or three days after the operation, while ligation of the inferior thyroids is not only more humane but safer because of the absence of postoperative pain which increases the reaction. This latter is accomplished by section, posterior to the sternocleidomastoid muscle in front of the scalenus, passing beyond the great vessels by reaching the inferior thyroid artery as it leaves the thyroid axis. There is practically no pain and consequently the reaction is less than in ligation of the superior thyroids.

The medical treatment is extremely important and every surgeon should see that it is properly carried out after operation. In our experiments with feeding the desiccated whole gland (made by three of the best known manufacturers) to dogs which were thyroidectomized or had the thyroid transplanted into the spleen (to "denervate" it) this desiccated thyroid produced albumin or glucose or both in the urine within two or three days. Preparations made from fresh thyroid, which are now generally available like the thyroid nucleoprotein material or the thyroid residue, which can be given hypodermically, seemed on the other hand entirely "nontoxic"—clinically these "fresh" derivatives are far preferable to the usual dried powder or tablets. I have found it best to feed the nucleoprotein derivative or thyroid residue to overcome the hypothyroidism and prevent reversion to the hyperthyroid state. If too much drive persists, that is, if the patient is sweaty with too much gastrointestinal or vasomotor drive, feed adrenal extract preferably the adrenal residue (not adrenalin) to check the gastrointestinal disturbance and help the thyroid hold iodine. The hyperthyroid gland seems unable to hold or to metabolize a normal amount of iodine. In postoperative, acute exacerbations, or when immediately after operation the patient manifests lack of drive and high temperature, I have saved some patients by giving hypodermically twenty-five or thirty minims of thyroid residue every four to twelve hours. The alveoli in the glands in fatal cases are filled not with colloid but with a mass of cells and granular material. The skin and tongue are dry and the symptoms are those of failure of the gastrointestinal tract. If the condition lasts long enough the liver enlarges and there is jaundice. The thyroid residue experimentally stimulates the gastrointestinal drive and so when this fails, as it does in postoperative exacerbations of hyperthyroidism, the thyroid residue is beneficial. It slows rather than accelerates the heart.

In closing, as a suggestion concerning the physiology of what happens in these cases, I believe the condition is due to a disturbance of body chemistry more complex in its nature than too much thyroid secretion. There seems to be too little. Death is apparently due to a failure in the nervous and chemical balance which constitutes the automatic drive and check system regulated by the involuntary nerves.

Results of Treatment in One Hundred Consecutive Cases of Hyperthyroidism

By HUGO A. FREUND, M.D.,
Detroit.

During the past few years unusual interest has been manifested in the study of diseases of the thyroid gland. Following the work of Kocher, Marine, Plummer, *et al.*, investigations concerning the etiology and treatment of diseases of the gland have naturally increased. This interest has been heightened in the past few years by the work of Du Bois in calorimetry and by the simplification of methods for study of basal metabolism by Benedict. These have been of especial value in stimulating studies in hyperthyroidism. Hence, the present time finds clinicians quite generally applying these methods of investigation in their routine hospital and private practice.

The original observations of Parry, Flajani, Graves and Basedow were accurate descriptions of exophthalmic goitre. Though Parry's writings are the earliest, the disease is generally known under the name of Graves's and of Basedow's disease. The syndrome that falls under these titles has been accepted as categorically descriptive. There has been no differentiation of types of the disease. In 1893, Greenfield reported histological changes in the thyroid that he considered the cause of hypertrophy of the gland as well as the basis for symptoms of the disease. Marine had previously called attention to cases of exophthalmic goitre in which not all of the signs were present, but in which a few were effaced, the remaining ones being just sufficient to permit of recognition of the disease. He called these cases the *formes frustes*. Some designated them as secondary types of goitre. Others had described them under captions of indefinite forms of nervous disease. In the meantime, various writers added minor details to the description of the exophthalmic goitre, notably, Moebius, Graefe, Gauthier, Stellweg, Jellinek, Dalrymple, and Buschan.

Following the opinion of Moebius, most observers came to regard exophthalmic goitre as due to hyperactivity of the thyroid gland. This hypothesis, though finding much in its favor, did not account completely for all the changes wrought by the disease. For example, thyroid feeding produces many of the signs of thyrotoxicosis, although exophthalmos does not develop. Though experimental thyroprival myxedema in the sheep is symptomatically the antithesis of hyperthyroidism, the administration of the serum of these thyroidectomized animals does not eliminate the symptoms of exophthalmic goitre. Evidently other factors besides pure hypersecretion of the thyroid are essential to the production of the signs and symptoms of hyperthyroidism. Kocher and Crotti called attention to the part played by the thymus gland. The effects of the disease upon other glands of internal secretion have been frequently observed. Cramer and Krause showed the action of thyroid substance upon the demobilization of glycogen in the liver. Cannon demonstrated the effect of changes of parts of the sympathetic nervous system upon the thyroid. These then are among the observations that have proven that hypersecretion alone is not the sole factor in producing the complete syndrome of Graves's or Basedow's disease.

Studies in the pathological alterations in the hyperthyroid gland following Greenfield's description in 1893 have been notably those of Kocher, MacCallum, Lewis, Wilson, and Marine. Plummer in 1912 was the first to maintain that a specific change existed in the exophthalmic goitre. He pointed out a parenchymatous hypertrophy and hyperplasia of the gland. This he considered an entity in contradistinction to the thyroid adenoma, which may or may not produce an excessive secretion with symptoms of hyperthyroidism.

He states further that the symptomatology of the two conditions is different. 1. In the hyperplastic goitre, exophthalmos is relatively frequent; it rarely if ever is seen in the adenomatous type. 2. The time of life that the goitre developed is earlier in the hyperplastic than in the adenomatous type. 3. The average rate of onset of symptoms following the initial appearance of the goitre is far more rapid in the hyperplastic than in the adenomatous gland.

At the same time points of similarity between the two types of the disease were pointed out: The tremor, the tachycardia, the nervous manifestations, sensitiveness to epinephrin (Goetsch), skin changes and heat production. The latter is of additional importance because as we know, it serves as the means of determining the severity of the disease. This is the one constant outstanding feature of the disease. And it is only in the last few years that the importance of this fundamental point has received adequate study and emphasis. Though Friedrich Müller in 1893 showed that the Basedow patient lost weight and nitrogenous substances on an adequate diet, Magnus Levy in 1895 established the fact that the energy requirements in exophthalmic goitre are increased from fifty to seventy per cent. above the normal. In 1916 DuBois's studies followed by the work of Benedict, Boothby, Sandiford and others, showed that the determination of the basal metabolic rate is the most reliable index of the presence of hyperthyroidism, the severity of the disease, and the progress of the condition as influenced by various forms of treatment.

Since 1917 numerous writers have reported their observations in diseases of the thyroid gland. Their work has been directed toward the problem of more satisfactory therapeutic measures. Surgery, though having made great progress, has not definitely met and overcome all the conditions presented in the disease. Even at this time the most enthusiastic supporters of lobectomy and ligation frankly confess that not all the indications for cure have been met, by reducing the vascularity and by excision of the parts of the diseased gland.

Naturally nonsurgical methods have been suggested from time to time. A great variety have been recommended. Chief among these measures have been prolonged rest, the x ray, radium and internal medication. This has finally led to attempts to rationalize therapeutics and particularly to place the true value upon any procedure. The study of hyperthyroidism by controlling progress with basal metabolic studies has made this possible. Those who have studied the problem from this viewpoint are notably Melans and Aub, Janney, Grier, Lueders, McCaskey. They have pointed out the practical value of the management of hyperthyroidism by nonsurgical methods when controlled by studies in basal metabolism.

During the past two and a half years the material which forms the basis of this paper has been carefully collected for study. The patient of the last case of this series was seen September 1, 1921, so that at least six months has elapsed since any of them were under treatment or observation. This has allowed for a reasonable time to elapse during which failures in treatment and relapses so often observed could have taken place. There are one hundred cases manifesting various types and degrees of hyperthyroidism. They fall, broadly speaking, into three groups: 1, the functional; 2, the adenomatous; 3, the hyperplastic.

Group 1 constitutes those cases in which the symptoms of thyrotoxicosis are mild or moderate. The thyroid is slightly enlarged or in some instances no appreciable change is noticeable. Loss of weight, fatigue, tremor and palpitation are complained of. Eye signs are absent. Sleeplessness, irritability, fears, depression, flushing are among the nervous manifestations. Such patients are rarely if ever prostrated. Sometimes they are more active than usual as if reacting to constant stimuli. Diarrhea and other gastrointestinal symptoms are rare. Menstrual disturbances are often present. Trophic changes are never seen though vasomotor phenomena are frequent. In every case the basal metabolism is increased.

The etiological factors of this group of cases are as numerous as they are varied. Focal infections without producing active thyroiditis are the cause of many cases.

There are twenty-three cases in this series. Puberty is the inciting factor in a certain number, overaction of the thyroid occurring before the proper balance has been established. The climacteric for a like reason may be held responsible for eleven cases. Fright and shock, such as have been produced experimentally by Cannon, definitely account for four cases. Then there are a few cases in which gastrointestinal disturbances play a rôle. These are an indefinite class of cases. Chronic constipation, perhaps cecal stasis, may be the factors. The mechanism is certainly in doubt. Whether it be due to absorption or reflex through irritation of the abdominal sympathetic, no statistics or data cover the question. It is out of this functional group that further differentiation will doubtless be made in the future and it is probable that in some instances the causative factor will be determined.

Of the second group of cases that I wish to speak a history of previously existing enlargement of the gland is always to be obtained. This swelling of the gland may have been present for many years and caused no disturbance other than local irritation or pressure. One of two things may occur. Suddenly following some inciting cause, such as an infection, an injury or fright, symptoms of thyrotoxicosis are ushered in with more or less secondary manifestations. In this the causes are not in any sense different from the functional group, except that an adenoma has been definitely present. However, adenomas become active frequently without any discoverable excitant. In these the symptoms are quite intense and resemble, in many features, the hyperplastic type of goitre.

In the majority of cases of adenoma, however, the onset is slow and gradual. Loss of weight may be the first thing to be noticed. Restlessness may soon follow with trembling and some breathlessness on exertion. This is attributed to a sense of palpitation which increases the patient's anxiety and often produces sleeplessness. Then comes a feeling of continual warmth, the bedclothes are too heavy, the rest of the family seem to need more covering or clothing than the patient. Gastrointestinal symptoms, if any, are usually excessive appetite. If the disease progresses the circulatory system suffers chiefly. The heart hypertrophies, extrasystoles develop and hypertension soon supervenes. The end result may show myocardial degeneration with edema and failing.

The most severe cases of hyperthyroidism from the point of view of the acuteness and the intensity of symptoms are the hyperplastic group. Though the syndrome developing upon the basis of an adenoma may progress so far as to damage irreparably a circulatory system and leave the patient a hopeless invalid, the hyperplastic patient usually seeks relief before the heart or the vascular system has been as severely damaged. In these patients the tremor is coarser and tachycardia is more violent; sweating and vasomotor symptoms are marked; exophthalmos with attendant ocular manifestations—Graefe, Stellwag, Moebius signs—are the rule, gastrointestinal symptoms of nausea, vomiting and diarrhea are common, emaciation is rapid and the thyroid is highly vascular as evidenced by thrills, bruits and pulsations. The onset of this group of thyrotoxicoses is difficult to explain. The pathological picture is something different than occurs in any other known disease. In some glands areas of small round cell infiltration are seen that suggest that the disease is either the result of an infection or the reaction to one. In others the hyperplasia almost reminds one of the tendency to malignant proliferation that is seen in a deciduoma. The physiological response in this type is intense. The metabolic rate is always greatly augmented. There is often a period in the course of a particular case during which severe exacerbations occur. In cases of this type that become chronic there frequently develop trophic changes in the skin or the hair and nails, or other signs attributable to secondary endocrine disease are manifested.

Before we turn to the consideration of treatment in these three classes of cases a word should be said regarding the similarity of some of the individual findings in the three groups. Tremor, tachycardia, weight changes, vasomotor phenomena are common symptoms. To these should be added sensitiveness to epinephrin, increased heat production and lymphocytosis. The Goetsch test is of undoubted value though it is not without danger especially in cases of cardiovascular disease with hypertension. There has been one sudden death from it in my observation. The study of the basal metabolic rate is a method of precision and refinement that not only differentiates the hyperthyroid case from the neurocirculatory case, and the tuberculous patient but also is the means whereby the treatment can at all times be under accurate supervision. I may mention here that the total and differential white count is too frequently neglected as it gives valuable information. Neutrophilic leucopenia with absolute as well as relative lymphocytosis is the rule.

The basis underlying the treatment of hyperthyroidism demands a reduction in the increased metabolic rate that is producing the loss of nitrogen through increased tissue destruction and the exhaustion of the nervous system through the effects of the toxin upon the sympathetic system. Where the primary etiological factor that has activated the thyroid mechanism cannot be sought out and removed, direct attack must be made upon the thyroid structure and upon the thyroid function, so that these may be brought within their normal limits. Naturally where thyroid dysfunction has been found to be due to an increase of thyroid tissue, such as we see in the adenoma and in the hyperplastic gland, surgical methods that will make the proper quantitative reduction have long been advocated and employed. However, for various reasons surgical intervention has not always been possible, expedient or successful. The simple procedure of rest alone has often so reduced the patient's increased metabolism, as to restore a normal function to the gland. Then, too, there are drugs, mostly sedatives, which have had their advocates. Of all of them but one has really deserved attention, because its action is on a rational basis. I refer to the quinine salts—originally urged by Forchheimer for its value in hyperthyroidism in the form of quinine hydrobromide. Pharmacologists have long pointed out that quinine definitely lowers the metabolism. With modern methods of studying the basal metabolic rate, it is an interesting experiment to see how the basal metabolic rate may be reduced by the administration of this drug. Hence, there is a rational basis for the use of quinine salts in the treatment of hyperthyroidism. In my cases, it has been uniformly given as a part of the treatment with satisfactory results.

Ever since the destructive effect of the röntgen ray has been recognized, it has been used in one form or another in the treatment of thyroid disease. Its valuable effects have been recorded at various times. However, only within recent years has a systematic study of such cases been pursued. The controlled use with definite dose of the x ray has made such studies statistically reliable. Checked up by frequent basal metabolism studies, its effect can be so carefully observed that it forms a method of treatment both safe and simple. My conclusions from its use in one hundred consecutive cases, which have been under observation for from six months to three years, are that in the majority of cases it promptly and effectively destroys portions of the gland producing thyroid hyperactivity; that failure to give complete relief does not interfere with subsequent surgical removal of large, hypertrophied, adenomatous portions of gland and that its control places its value as a remedial agent, far above the surgical method of removal of uncertain amounts of the diseased gland.

CONCLUSIONS.

1. It has been the object of this paper to differentiate the three groups of hyperthyroidism, the functional, the adenomatous and the hyperplastic.

2. They can be divided into these types clinically without difficulty if one obtains a careful history of the onset of goitre, the beginning of symptoms, examining the thyroid critically and noting the eye signs and the cardiovascular system.

3. Transition forms are not infrequent and should be definitely considered. It must be borne in mind that there are cases in which there are outspoken signs and symptoms of hyperthyroidism, without glandular changes, or at the most, colloid goitres without adenoma or hyperplasia. These are due to temporary functional hypersecretion.

4. The medical treatment of the hyperthyroid cases with x ray controlled by metabolism studies, proper rest and the use of quinine is a satisfactory manner of managing a great proportion of cases of hyperthyroidism.

5. The results are apparently permanent and where slight reductions have a tendency to occur, the institution of supplementary treatment suffices to arrest the progress of the disease.

Comparison of Basal Metabolic Rate with the Histopathology in Thyroid Dysfunction

By JAMES B. RUCKER, JR., M.D.,

Toledo, Ohio.

In seventy-five cases coming under the surgical care of Dr. S. J. Waterworth at the Clearfield Hospital, Clearfield, Pa., during the period from June 1, 1921 to July 1, 1922, in which subtotal thyroidectomy was resorted to, microscopic sections have been made and examined histologically. The histological diagnoses have been charted in a comparative way with the basal metabolism of the patients before operation in an attempt to determine whether there existed any relation between the basal metabolism estimation and the several histological types of thyroid dysfunction.

All determinations of the basal metabolism of these patients were made with the large Sanborn-Benedict apparatus.

We notice in these cases in which only the histopathological diagnosis of follicular distention was made, a basal metabolic rate ranging from minus one to plus 211. With the exception of two, however, which showed clinically great toxicity, we may safely say that ordinarily these cases of colloid goitre presented a basal metabolic rate ranging from a normal to a moderate hypermetabolism. This corresponds closely to the clinical symptoms as seen in colloid goitre in which there is apparent, as a rule, little evidence of toxicity.

Follicular distention associated with adenoma gives a very moderate hypermetabolic rate, and here also we note clinically very few toxic symptoms. The basal metabolism ranges in our series of cases from plus eighteen to plus twenty-six.

Among the purely adenomatous conditions as determined grossly and from histopathological examinations, we found the metabolic rate ranging from a plus eleven and plus fifteen, slightly above normal, to a severe degree, plus seventy-one, the usual being from moderate to high. One case of adenoma with sclerosis showed an excessively high rate, plus 103.

In the cases of hyperplasia of the follicles in association with hyperplasia of the follicular epithelium, the range of the basal metabolic rate was between a moderate and a very high degree, depending largely upon the amount of hyperplasia of the follicular epithelium. Rest in bed for six weeks before operation reduced the basal metabolism in one of these cases from plus eighty-nine to plus thirty-three.

In the cases of adenoma with which follicular hyperplasia was associated, we found the range of metabolic rate between minus twenty-nine and plus eighty-seven. From plus twenty-five to plus seventy-five however, would include the usual run of these cases of adenoma with follicular hyperplasia.

In the series were three cases in which there appeared such an extreme degree of follicular and epithelial hyperplasia as to present grave suspicion of malignancy, although the basal metabolism showed but a moderate rate. In the first case three tests were made, one before rest in bed for three weeks which read plus eighty-eight; the second after three weeks in bed and before ligation reading plus fifty-two; and the third, after bilateral ligation of the superior thyroid arteries being plus forty-four. The other two cases of this group gave a basal metabolic rate of plus thirty-six and plus forty-eight respectively.

Four apparently normal thyroids, as far as could be determined by gross and histological examinations, gave basal metabolic rates of plus five, seven, eight and fourteen, respectively, which are all within the normal limits.

The conclusion that one would naturally draw from this brief summary of seventy-five cases of thyroid dysfunction, is that the histological type of thyroid disorder cannot be prognosticated by determining the basal metabolic rate alone and, although the basal metabolic rate and the toxicity of the patient correspond very closely, yet by neither one nor the other alone can the histological picture be prejudged.

Comparative tables are appended herewith, one showing how the cases having the same grouping according to the basal metabolic rate vary in their histological characteristics; the other, in which the cases are grouped according to their histology and setting forth the marked variation in the metabolic rate.

The Goitre of Adolescence*

By JEROME SELINGER, M.D.,
New York,
Assistant Professor of Surgery, New York Post-Graduate Medical School and Hospital.

In attempting to classify the various types of enlargement of the thyroid gland certain difficulties will be met when one aims to have the pathological and clinical classifications agree. This discrepancy, of course, implies that we have not yet perfected our analysis of this very interesting gland. The classification given below (1) is as nearly complete as is possible with our limited knowledge.

- I. Goitre with hyperthyroidism.
  - a. Goitre of adolescence.
  - b. Graves's disease.
  - c. Adenoma.
- II. Goitre without hyperthyroidism.
  - a. Simple or colloid goitre.
  - b. Adenoma.
  - c. Various degenerative forms.
- III. Malignant goitres.

The goitre of adolescence is often included in the group known as colloid goitres. Such a classification is chemically correct, for the colloid content of the gland is undoubtedly increased. However, the usual goitre of adolescence presents such an interesting picture and follows such an interesting course that it may be well to describe it as a distinct entity.

It is not the purpose of this paper to discuss either the physiological or the pathological anatomy of this condition. For such an exposition one is referred to the standard textbooks on the subject or to the various exhaustive papers of Kendall, Plummer, and others, which appear at frequent intervals in the various medical journals. It is sufficient to say that in the early stages of this disease, before it is generally recognized,, the colloid content of the gland is decreased. Later, of course, it is increased, and the acini within the gland are dilated, lined with low, flat epithelium, and filled with this colloid material.

---

*From the surgical service of Dr. Charles Gordon Heyd.

Diseases of the thyroid gland occur throughout the world. There are certain areas, however, called goitre districts or goitre belts where the disease is much more prevalent than in adjoining regions. The Himalayas and the Alps are the most important goitre districts on the Eastern Hemisphere; the Great Lakes Basin and the Cascade Mountains of Washington and Oregon are the most important ones on the Western Hemisphere. Goitre appears to be on the increase and they are found in large numbers in districts far removed from the socalled goitre belts, districts that at one time were thought to be immune.

Because of its accessibility, the thyroid gland has perhaps had more study than any other internal secreting organ. In spite of all this research work the ultimate cause of the goitre of adolescence is not known. Its immediate cause has been definitely shown to be due to a deficient amount of iodine. This iodine deficiency is undoubtedly due to a disturbance of the iodine metabolism which, under normal conditions, should maintain an equilibrium. In other words, iodine catabolism exceeds iodine anabolism and a deficit is created. Whether the goitre districts lack iodine in their food, the water or the air, has not been determined. Ordinary food contains such a negligible amount of iodine that it need hardly be considered. Furthermore, an analysis of food in goitrous districts has shown it to be on a par with food grown where goitre is almost unknown.

That goitre is a water borne disease is a theory almost as old as the disease, and it cannot be cast aside as being unsound. Iodine is derived originally from the sea and the goitre districts are all mountainous. There is room for considerable research work along this line.

The thyroid gland contains a very much greater amount of iodine than any other organ in the body. It is, as it were, the storehouse for iodine which it discharges into the circulation by means of the lymphatics as the various metabolic demands of the body may require it. With these facts in mind it has been suggested that the goitre of adolescence may occur in one of two ways. First, normal metabolism in an individual with a deficient amount of iodine; second, increased metabolism in an individual with a normal amount of iodine.

At the beginning of the paper it was stated that goitre is on the increase. In this connection it is interesting to note that a large number of the female population of this generation is engaged in business and other varieties of labor. This is a condition that has not existed heretofore. The body economy of these individuals, as far as we know, is the same as those who have gone before them. But they are living and working under totally different conditions. After a hastily gathered breakfast they rush off in the crowded cars and subways to their work. They are under tension most of the day with a short interval for lunch. They travel home under conditions similar to those under which they came to work. They probably spend most of the evening and night at the moving pictures, dancing or otherwise playing about. An additional noteworthy fact is the preponderance of meat in the diet of these people. In conjunction with these facts, and in some instances because of them, the bowel hygiene becomes bad, the eyes are strained, and the teeth and tonsils become diseased. All these factors tend to produce both nervous and physical exhaustion.

Such a strain upon the body is bound in time to alter the orderly discharge of its duties. An increase in energy demands an increase in metabolism. An increase in metabolism means an increased catabolism of iodine. If under these conditions the body calls for more iodine and it is not forthcoming from the normal gland, then the thyroid must enlarge to furnish it. Girls of this kind can be seen in large numbers on any of the crowded business streets of New York. They represent a distinct type with a peculiar constitutional appearance. They are generally thin, quick, alert, and sensitive with a full or an enlarged neck. They weep easily, have a poor and capricious appetite, sallow skin, complain of constipation and of irregular, scanty and painful menstruation.

It would seem that the enlargement of the gland under these conditions is purely a compensatory one. More iodine is required to supply the needs of the body and the iodine factory and storehouse enlarge to meet the demands.

It may not be out of place to mention here the intimate relationship between the thyroid gland and menstruation. It has been known for centuries that the gland enlarges just previous to the flow. It is also an established fact that the necks of young virgins are larger in diameter than those of women who have had sexual intercourse. In the old days among certain tribes it was customary to measure the bride's neck previous to her marriage and on the morning following it in order to determine whether or not she had had sexual intercourse. (Havelock Ellis.)

In the majority of cases the goitre of adolescence produces few or no symptoms. The patient, usually a female between the ages of fifteen and twenty, informed by a relative or friend that her neck is slightly or considerably enlarged, consults a physician. This enlargement is uniform. On palpation it is found to be soft, of a smooth, even consistency, and without any nodules. This bilateral uniform enlargement may be the patient's only complaint and the sole reason for her consulting a physician.

On the other hand, if the enlargement has existed for a number of years, during which time the patient has continued to live at top speed, then other symptoms make their appearance. She will begin to lose weight, show a poor muscle tone, fatigue easily, become sallow and constipated. She is also nervous and highstrung and has tachycardia upon the slightest exertion. With certain degenerative changes that may take place in such a gland other symptoms indicative of such change are superimposed upon those already mentioned. Such a gland very readily develops into a true toxic goitre or Graves's disease.

In any patient with an enlarged neck it is always important to determine the basal metabolic rate. If it is found to be approximately normal then you may be nearly positive that you are not dealing with a true toxic goitre. The patient with a goitre of adolescence should have a normal or a slightly plus basal metabolic rate. The literature on basal metabolism is still in its infancy. So many factors must be taken into consideration in order to determine a reading that errors are prone to occur. One must allow for these errors when the basal metabolic rate is a determining factor. Lusk has briefly yet completely defined the basal metabolic rate as "the minimum of energy compatible with cell life."

Usually the goitre of adolescence undergoes a spontaneous cure, and after a varying number of years the person is once again normal in all respects. This would appear to be due to the fact that the patient leads a more orderly life and the increased iodine formerly so necessary is no longer called for. The size of the gland is accordingly reduced. An additional factor that tends toward a spontaneous cure is natural biotic retrogression.

Instead of a spontaneous cure the gland may at any time undergo one of the following forms of degeneration: cystic, true colloid, or adenomatous. The calcareous and malignant forms of degeneration rarely occur in early life. These generative forms as a rule produce no symptoms unless they are sufficiently large to exert pressure upon the surrounding structures. It is asserted by some that the adenomatous type of goitre, when present, existed as such originally due to some fetal rests that were encapsulated. These have remained dormant for many years and then have started to grow slowly.

The treatment of the goitre of adolescence is not difficult provided you have the complete cooperation of the patient. The splendid work of Marine and Kimball has conclusively demonstrated that small doses of iodine over a comparatively short period of time will reduce the gland to its normal size. Iodine in any form may be used. Sodium iodide,, for example, given in five grain doses twice daily for a month or two should suffice. If the gland does not become smaller under such treatment the probable indications are that you are not dealing with a simple goitre but with one of the mixed types that are often found in which an adolescent goitre is associated with a small adenomatous growth of the thyroid. When such goitres are treated with iodine the colloid portion generally disappears and the goitre is reduced in size, but the adenoma remains and is then more easily recognizable. (Sistrunk.)

In conjunction with the iodine treatment good hygiene and dietetics must be insisted upon. The patient should lead an orderly life with at least eight hours of sleep each night. The diet should be rich in carbohydrates and the bowels should be moved regularly each day. Too much emphasis cannot be placed upon this latter point for a great majority of the girls of this generation are constipated. McCarrison records some interesting experiments which very closely link intestinal stasis with enlargement of the thyroid gland. He quotes Lane who, in such a case, performed a shortcircuiting of the bowel for the constipation, and the goitre disappeared. His further experiments with the bacterial flora of the large and small intestines deserve considerable attention.

The teeth and tonsils should be regularly inspected and any disease of these structures should be promptly treated. Calcium, being an important factor in metabolic disturbances, will be of distinct benefit if given with the iodine. This latter fact is evident when we realize that in goitre there is true calcium catabolism. It is well known that the thyroid gland exercises an important influence over calcium metabolism. This is probably closely related to other endocrine organs.

The goitre of adolescence is not a surgical condition. To consider an operation upon a gland of this type is worse than failing to consider one for a toxic goitre.

Endocrines in Gynecology

By J. THOMPSON SCHELL, M.D.,
Philadelphia,
Gynecologist to the Northwestern General Hospital.

According to some writers "viewed in a broad sense, every organ and tissue in the body possesses an internal secretory function," for each one gives off to the blood stream one or more substances capable of influencing the organs and tissues far distant in the body. In the case of the socalled ductless glands, the internal secretion is characterized by certain more or less striking and specific effects.

The designation of endocrine organs would seem to be preferable to that of ductless glands, for the function of the internal secretion is not confined to the glands which possess no ducts. According to other writers, the best example of a gland possessing both external and internal secretions is the testis. To the same group belong the ovary, if we look upon the periodical discharge of ova as a species of external secretion.

As this paper is to be confined to the endocrines in gynecology, it will be necessary to review as briefly as possible the modern conception of menstruation, which is based on the belief that the ovary gives off a secretion which is responsible for this phenomenon.

Halban has brought forth evidence, both experimentally and clinically, which seems to point the fact that the ovaries are really only activators to the real underlying cause of menstruation, but his work does seem to prove the ovary is a real factor in producing menstruation, whether directly or indirectly. The impulse starts from the ovary and is carried by the blood stream and is therefore classed among internal secretions or hormones of the body.

There has been much discussion as to which portion of the ovary produces this important hormone, the follicle, the stroma, or the corpus luteum. The evidence seems to point strongly to the corpus luteum. The father of this theory was Gustav Born, and his pupil, Frankel, has placed it on a strongly experimental basis. Dr. J. G. Clark takes the position that the corpus luteum function is to stimulate the blood supply of the ovary.

If it was possible to isolate the active hormone of the corpus luteum and by injecting it into the blood bring about the characteristic premenstrual hypertrophic changes in the uterus, the problem would be solved, but the use of corpus luteum extract either by mouth or by injection has not been altogether convincing. The matter is more complicated by the fact that the function of the corpus luteum appears to vary at different stages of development. The question, therefore, must be regarded as an open one.

No consideration of the physiology of menstruation would be complete without the assumption that there is some local factor in the endometrium which in some way increases the permeability of the bloodvessel during menstruation. This is closely bound up with the question of why menstrual blood is noncoagulable. In the final analysis, however, it seems probable that the formation of this substance, be it hormone or enzyme, is dependent upon the ovary, and may as Sheickel's work indicates be formed in the ovary and given off by the endometrium.

That the ovary is fundamentally important in determining sexual characteristics is sure, but it must be emphasized that other endocrine glands, especially the thyroid and the pituitary, play a very important contributory rôle and that these glands are greatly influenced one by another must always be kept in mind.

To me the literature on endocrinology is not without humor. The more the contributions of various writers are compared the more contradictory the evidence seems. One very enthusiastic writer goes so far as to say that we are nothing but a balance of our endocrine reactions, and it seems to me that it will be only one step into the future to see added to the other socalled schools of medicine that of endocrinopathy, or something like that. Let me call your attention to the words of Sajous: "If our object to place pharmacology on a scientific footing is ever to be realized we should insist, whenever an agent is to be tried therapeutically, upon a preliminary determination of its identity as a chemical body. Thus only will it be possible for us to establish its physiological action on a solid basis. In drug therapy, this important feature has been carried out to a considerable extent, and what we know of the physiological action of most agents derived from plant life has been acquired since their active principles have been isolated and made the basis of experimental and clinical study. Just as opium contains various principles—morphine, apomorphine, codeine, etc.—so do animal extracts contain a multiplicity of substances, cellular and plasmatic, and also products of cellular metabolism capable of provoking physiological effects; but here very little effort has been made to isolate the truly useful principles. Hence, the confusion and empiricism which has always surrounded the use of these agents.

"All this applies to organotherapy as it does to pharmaceutical agents. It is unquestionably true that we have among the twenty and odd animal extracts that have been proposed a few, at least, which are capable of affording relief where no other class of agent will act—thyroid preparations in myxedema and cretinism, and adrenal extractives in Addison's disease and hemorrhage, for example. The adoption of a systematic line of study in the direction proposed seems to me to facilitate the discovery of additional useful applications of these agents, or, at least, to give their use in practice a more rational basis.

"Important in this connection is the identification of the true organotherapeutic preparations. By the true agents I mean those which can be used intelligently, with knowledge of the physiological effects produced for the reason that their active principles are known. Thyroid extract belongs to this class, since we know that its action is due to the iodine in organic combination its secretion contains. Adrenal preparations likewise are included because their active principles, whether epinephrin, suprarenalin or adrenalin, are also known. Conversely, we have a large number of organic preparations that are used blindly, without knowledge of their components, which may number from five to twenty or more, in almost any disease related directly or remotely with the organ from which the extract is obtained. Mammary extract can be cited as an example of these agents. They are hardly entitled to a rank much above that of empirical nostrums until rendered fit, by their sponsors through chemical, pharmacological, and clinical researches, to be taken up by the profession as legitimate pharmaceutical agents.

"When it is remembered that almost any organic substance will in some way or other affect the blood pressure, and when we consider that all tissues contain more or less nuclein, intermediate, and therefore toxic, wasteproducts, red and white corpuscles, and many other substances capable each in its own way of evoking some sort of reaction when injected into animals, the actual value of such experiments is reduced to nil. It is about as scientific as the giving of hashed ear for earache."

No one has, as yet, been able to isolate any active principle from the ovary or really to prove that it manufactures an internal secretion. I have removed the ovaries from women of all ages and in the majority of the cases, so operated upon, I have failed to see the alarming symptoms that have so vividly been described by so many physicians. In fact, I have had much better results by a total removal of the ovaries than I have had by the socalled conservative method, and while I am not in favor of removing the ovaries as a routine procedure in pelvic disease, I fail to see anything but good result following a clean pelvic operation, and I have had many nervous and disappointed patients where a partial ovariotomy had been performed and very frequently have seen second operations become necessary. According to Lowey and Richter, removal of the ovaries reduces the oxygen intake ten per cent., and this may explain some of the postoperative symptoms following double oophorectomies.

My personal experience in the use of ovarian extracts and corpus luteum on the whole has been disappointing and unreliable, and I can never prescribe their use with any real confidence in the results, and the indications for their use are never clear or definite. I have had some really good results in the use of both ovarian substance and corpus luteum in postoperative treatment, following double ovariotomy, and also some fairly satisfactory result in the nervous phenomena of the menopause of climacteric period, but on the other hand I have many cases that have shown no results from the same line of treatment and in fact the symptoms have apparently been somewhat exaggerated. I can hear some expert (?) endocrinologist say that this was due to improper application of the various internal secretions or the wrong combination of endocrines, but be this as it may, I am inclined to think that no one as yet can say just how these various socalled endocrines can be used with a hope of a reliable and definite result, and, as quoted above, until some definite chemical substance can be isolated and studied, the whole subject will continue to be empirical and confused. If the corpus luteum function is to stimulate the circulation, and therefore the activity of the ovary as suggested by John G. Clark, then theoretically corpus luteum would be useless in women whose ovaries had been removed, but I am confident that I have had more and better results from the use of the corpus luteum extract, both by mouth and hypodermically, than I have ever had from the ovarian substance itself.

That endocrinology in gynecology will be increasingly useful is to be hoped for and expected, but let us not be carried away and overenthusiastic on this subject as overenthusiasm is always followed by a reaction that spells therapeutic nihilism.

The future of ovarian substances, hormones or extracts must be worked out by the physiological chemist, placed on real scientific basis before we can hope for an established place for these substances in our everyday therapeusis.

Let us therefore be willing to help by constructive criticism and careful clinical observation, but not to be carried away by improbable and unscientific reports of the overenthusiastic endocrinologist.

2102 Spruce Street.

Present Day Considerations of the Thyroid

By JOHN B. HAEBERLIN, M.D.,

Chicago.

During the past score of years thyroid surgery has been progressing and improving probably more than that of any other organ that is the focus of surgical attention, it being the one ductless gland that has been courted surgically and has up to the present carried away the honors. It is essentially a surgery of helpfulness. Up to the present time surgery for thyroid conditions, especially in adenomatous and hyperplastic types, is sovereign in its results and when performed early in these conditions results in cure in nearly all cases.

Recently the use of radium and the x ray has entered into the treatment of the thyroid, but these are of no value in the thyroid conditions of adolescence or for women during the childbearing period. As yet the dose of x ray and radium is difficult to determine. In their use each rests upon its own merits. After the treatment the progressive hypoplasia and gland degeneration ensuing is uncertain and undetermined in its amount. It therefore may produce an undue amount of damage resulting in myxedematous conditions, also increasing the connective tissue of capsule and cervical fascial layers of the neck making operative procedure more difficult.

At the larger clinics, especially those of Mayo and Crile, there is still a preference for surgery rather than for radium or x ray. This applies especially to adenomatous and exophthalmic types of goitre. During the last score of years the writings or literature on the thyroid have been voluminous and exhaustive. It has taken up especially the hypersecretion of the thyroid. There apparently is a swing of the pendulum to hyposecretion conditions of the thyroid, and it has been thought by many that the hypothyroidal condition is far in excess of the hyperthyroidism. The reason for the general impression that we have hyperthyroidism in excess is because the profession has focused its attention on this condition, and when it is established it is much more easily diagnosed than the beginning hypothyroid condition. The literature abounds in the different types and pathology of thyrotoxicosis along with its symptomatology and clinical signs. The treatment, especially the surgical treatment, has been thoroughly discussed and perfected, but one finds at the present time attention being focused on the prevention of simple goitre. The condition of goitre as it exists in different countries and communities has been recognized as a serious menace to the race. It has been taken up by legislative bodies and commissions appointed to investigate thyroid conditions and recommend treatment in different countries. It was as early as 1848 that the Sardinian government appointed a commission to study the condition of endemic goitre and recommend a method for its relief. France did likewise in 1864. Switzerland in 1908, and later Italy followed with their commissions on goitre. The French commission reported that France had 500,000 goitrous people with 120,000 cretins.

HISTORY.

Paracelsus, a Swiss physician, early in the sixteenth century, emphasized the relation between endemic goitre and cretinism. In 1825 Parry described a goitre syndrome; in 1835 Graves described a clinical complex with exophthalmic goitre; in 1840 Basedow's monograph on the same disease appeared. In 1874 Sir William Gull described a clinical complex of colloid myxedema and associated it with a lack of function of the thyroid gland. In 1880-1881 Kocher and Reverdin described a condition following total removal of goitrous thyroids which was interpreted as myxedema, confirming Gull's investigation in 1874. In 1877 Ord described a condition of subcutaneous mucoid deposition of tissue. This he considered to be a condition of myxedema. Horsley produced experimental myxedema in monkeys. Murray and Mackenzie in 1891 first administered thyroid extract to myxedematous patients and obtained definite therapeutic results. Magnus Levy in 1895 confirmed the findings of Mackenzie in 1891. In 1895 Bauman discovered that iodine was the normal constituent of the thyroid gland. In 1901 Oswald showed that iodine was not free but bound with globulin. In 1907 Marine emphasized that iodine is necessary to the normal function of the thyroid gland, that active hyperplasia of the gland is practically impossible if sufficient iodine is present in the system. In 1915 Kendall isolated an iodine containing hormone in crystalline form which he called thyroxin. The scientific analysis of goitre is distinctly of modern origin. However, goitre has been traced back to 2,000 years B. C. In taking up the historical side of goitre A. Hirsch has given us one of the most exhaustive publications in his *Historical and Geographical Relations of Goitre.*

ETIOLOGY.

The etiology of goitre is at the present time simply a speculation. There are a number of things or factors of which we are positive concerning goitre. The most outstanding factor up to the present time has been brought out by Marine, that it is a deficiency disease. He points out that iodine is essential to normal thyroid activity; from a chemical point of view any substitution for iodine destroys the physiological activity of the thyroid hormone; histologically glandular hyperplasia is due to a deficiency of iodine; the physiological action produced by thyroid extract is always in proportion to the iodine content. In experimentation, if iodine content is maintained above one tenth of one per cent. no anatomical changes toward goitre formation can take place. We have probable etiological predisposing factors in water, seashore and altitude. It is known that geographically considered our goitrous districts are especially removed from the sea shore. Many of our goitrous areas have a high altitude and many others are supplied with a water that is comparatively free from iodine. This apparently corroborates the iodine deficiency theory as a cause of the disease. Another causal factor is infection and it has many followers. McCarrison considers it a water borne infection belonging to the colon group of bacteria, and he has long championed the theory of a gastrointestinal infection as a goitre producing influence. However, he tries to reconcile the iodine deficiency condition by stating that the modified function of the infected gastrointestinal tract interferes with the normal absorption and assimilation of iodine.

Infections at any place throughout the body may produce a reaction in the thyroid producing activity, and in this way we may have the onset of a thyroid toxicity. This is especially true of the exophthalmic type or hyperplastic toxic thyroid. Age is especially a predisposing factor and we know that the adolescent lives through a critical period. The female carries a preponderance of approximately ten to one over the male and this, coupled with puberty, sex activity, pregnancy and menstruation, shows us the reason for its preponderance in the female, the thyroid being essentially a sex gland, so much so that it has been called an accessory ovary by Professor Osborne. Another cause is metabolic variation, this being associated with diet, as shown by the breaking down of glucose tolerance. There may be some balance in metabolism not yet discovered seriously influencing goitre. Heredity is considered by many to be a predisposing factor.

There is no doubt in my mind that different causal factors enter especially as regards the type of goitrous development. In certain exophthalmic types we have infection as the causal factor, the sepsis calling for an increased thyroid activity or a secondary involvement in the gland. We at times find cases which belong to this classification. Again, in the adenomatous types it is thought by many that the nuclei or adenomatous rests are congenital and as the person develops and call is made upon the thyroid these embryonal rests become active. I have had a number of cases in which it seemed certain that the gland developed from embryonal rests and these adenomatous types are especially common in families having a hereditary influence. There probably is no doubt that dysthyroidism in these cases is influenced or modified by one or all of the predisposing factors mentioned previously. These goitrous conditions are also modified by the hormonal balance occurring in the interrelated glands. Of this we have clinical evidence as may be observed by the influence of sex function, menses, pregnancy, and other activities upon the clinical picture in these patients.

Another predisposing factor of goitre is the overcrowding which may exist in rural districts as well as in the urbanized areas. Experiments on fish, performed by the Pennsylvania State Fish Commission during the years 1910-1911, show that goitre can be produced or prevented very definitely, the important factors being the overfeeding with artificial food, and, secondly, overcrowding. These two factors produce goitre in fish. Controls in nongoitrous fish showed that adding small amounts of iodine to the food or water and by remedying the overcrowding goitre did not occur. It has been thought by some that general debility predisposes to goitre also. Sex stimulation which may be of the subconscious type as it occurs in the pubescent years, such as uncontrollable longings, dreams and the like may be important factors. Sex stimulation and activity are associated with hyperemia of the thyroid. This has been especially noted in India. The natives judge from the thyroid enlargement whether their wives have been tampered with. Fright, worry, anxiety, grief are known for many years to be predisposing factors.

CLASSIFICATION.

With the advance of modern pathology of the thyroid gland the old textbook classification was discarded and it summed itself up as to whether we had a hyperplasia or a nonhyperplasia type, and with each of these types we had an atoxic or toxic variety. It was discovered that the clinician could prognose the type of thyroid that was extirpated with the exception of the hyperplastic atoxic type. Hyperplasia in the gland itself means toxicity, and the hyperplasticatoxic types of goitre were found to be very much less than one per cent., or so much so that many clinicians are of the opinion that the hyperplasticatoxic goitre is simply the beginning of the hyperplastic type of goitre before sufficient absorption takes place to produce clinical symptoms. The new classification, that is accepted by nearly all, is summed up clinically as simple or colloid goitre, adenomatous goitre, exophthalmic goitre, and physiological hypertrophy associated with adolescence, menses, pregnancy and allied conditions. This type is practically a forerunner of the simple colloid goitre.

DIAGNOSIS.

Given a goitrous patient the most important thing to determine is whether or not we have toxicity. In well established toxic cases the diagnosis is self-evident and we have in recent years been endeavoring to develop a reaction or technic that will aid us in our borderline cases. The most notable of these are the basal metabolism test, the Goetsch reaction, the Kottmann reaction and others. It would be ideal if we had a laboratory test which would tell or indicate to us the beginning dysfunction of the thyroid. Work along this line has been done by Rogoff and Goldblatt in an attempt to detect thyroid secretion in the blood of patients with exophthalmic goitre and other conditions involving the thyroid. Koopman, in the laboratory of the New York Health Department, has worked out a technic with fresh thyroid glands of dogs and guineapigs titrated against the serum of patients with toxic thyroidism. His idea is to determine toxic thyroids by a serum fixation test. Kottmann, a Swiss physician, has developed a reaction for thyroid activity. His technic consists of certain chemicals added to the blood serum and exposed to a strong electric light. The color changes determine his reaction. William F. Peterson, *et al.* determined that the Kottmann reaction was of value in all but three out of seventy cases of hyperthyroidism. The time will probably come when a laboratory method will be developed that will determine accurately beginning thyroid dysfunction and will be especially valuable in our borderline cases.

The basal metabolism test, if properly interpreted, has been accepted by the profession as having unusual merit and being an accurate index as to thyroid toxicity or activity if properly performed. The value of the basal metabolism test depends upon its correct reading and interpretation. Each case stands on its own findings. The status or physiological condition of the patient should be determined and correlated with the basal metabolism rates taken to determine its rise, fall or fluctuation.

Another valuable functional test in borderline cases is that of glucose tolerance. It is a test valued in diagnosis of mild hyperthyroidism or, in other words, in borderline cases. This has been worked out by Morris, Denis, Aub, Minot. In cases where we have the symptoms and physical findings which are suggestive of hyperthyroidism it is worth a trial.

BASAL METABOLISM.

Increased	*Decreased*
Hyperthyroidism	Hypothyroidism
Hyperpituitarism	Hypopituitarism
Fever	Asthenia
Infection	Especially those associated with myxedema

Nervousness simulating hyperthyroidism gives a negative test for the basal metabolism rate. The basal metabolism test is of greatest value in conditions simulating hyperthyroidism especially nervousness, irritability, heart neurosis and in our differentiation between early hyperthyroidism and neurasthenia. I am convinced that if we can interpret the emotional disturbance properly it will be of great help. A patient with hyperthyroidism is in a state of mental overactivity and there is inability to readjust the mind and the body to a state of repose. In the neurasthenic, on the other hand, any increased effort of mental or bodily activity produces the increased disturbance and exhaustion. The mental state of the hyperthyroid patient is optimistic, of the neurasthenic it is pessimistic. The crying of the hyperthyroid patient is usually without anguish or selfpity; with the neurotic there is usually anguish and selfpity. The irritability of the hyperthyroid patient is generally associated with an optimistic mental attitude while in the neurotic this irritability is associated with gloominess and plaintiveness.

The Goetsch reaction is simply based on the fact that the hyperthyroid patient is susceptible to adrenalin or epinephrin. In the last year the Goetsch test has not been so frequently reported but I believe it has a distinct value in borderline cases. This much we are certain, that in practically all cases its activity and intensity go hand in hand with our basal metabolism test. In a series of eleven borderline cases, in which four turned out to be pseudohyperthyroidism, the Goetsch test was negative in four cases as was also the basal metabolism test; in the remaining seven the basal metabolism and the Goetsch test ran hand in hand.

The thyroxin discovered by Kendall has a definite relationship to the basal metabolism rate. The function of the thyroid gland, so far as it is known at the present time, is the production and storage of thyroxin, and according to Klein is to deal particularly with the catabolism of protein poisons in the body. Another function is in its differentiation of tissues in the growing organism as demonstrated by the difference between the cretin and the normal individual. In conditions where the basal metabolism test is persistently below minus 16 to 20 myxedema develops. In thyroidless persons the basal metabolism rate may be kept normal by the administration of 1.6 milligrams of thyroxin given daily as shown at the Mayo Clinic. The basal metabolism rate should be used repeatedly to determine the effects of treatment, it being an index for determining medical, surgical, x ray or radium treatment.

PREVENTION OF SIMPLE GOITRE.

With the prevalence of goitre in children determined at fifty to ninety-five per cent. (Klinger of Zurich estimating eighty-two to ninety-five per cent., and in this country around fifty per cent.)—the prevention of development has been worked out by Klinger, Marine and Kimball, it being so simple as to arrest our attention and challenge the careless man to activity. Working upon the basis that simple goitre is a deficiency disease, considerable work has been done in this country by Moore, Kimball, Crile, the Mayos, Marine and Lenhart, and in Europe by McCarrison of England and Kocher of Switzerland. Kocher's statistics show eighty per cent. or more of the school children in Berne to be goitrous, coinciding with many of the goitrous areas in this country, and the recent clinical experiments among school children at Akron, Ohio, and elsewhere are confirmative of the work done in Switzerland by Klinger, so that at present the consensus of opinion is that simple goitre, especially in children, is a preventable disease when properly treated.

CONCLUSIONS.

1. It becomes the duty of every practitioner, specialist or general, who in any way comes in contact with children, at least to advise and recommend the proper prophylactic treatment of simple goitre.
2. Well established goitre (adenomatous and exophthalmic) should be subjected to the earliest proper surgical treatment. X ray and radium may be supplemental but should not supplant surgery.
3. It is advantageous to be on the alert for borderline cases, early diagnosis being a great help to the patient. In determining these cases great aid may be derived from, a, the basal metabolism test; b, glucose tolerance; c, adrenalin susceptibility.
4. Goitrous pregnant women should be given the benefit of the known aids concerning its prevalence.

On the Relation of the Spleen to Metabolism

A Review of the Literature

By JACOB ROSENBLOOM, M.D., Ph.D.,
Pittsburgh, Pa.

INTRODUCTION.

As it has been definitely shown that the removal of the spleen produces a varying degree of anemia, an increased resistance of the erythrocytes, and a lessened tendency to jaundice when hemolytic agents are given, it is apparent that the spleen must play a more important metabolic function than is usually thought. This paper presents a review of the literature as regards the influence of the spleen on metabolism.

METABOLISM STUDIES ON ANIMALS BEFORE AND AFTER SPLENECTOMY.

Eppinger (1) and King (2) have studied the fat content of the blood of normal and splenectomized animals and of persons suffering from diseases characterized by hemolysis. They found that the blood of dogs after splenectomy showed an increase of the total fats and of cholesterol, with a lowering of the iodine number, representing the unsaturated fatty acids. The cholesterol esters were variable. They assert that these results show the possible influence of cholesterol and of the unsaturated fatty acids in changing the conditions of hemolysis after splenectomy. Dubin and Pearce (3) in contradiction to the above have shown that splenectomy has no influence on the blood fat.

Richet (4) has shown that in order to maintain the weight of a splenectomized dog a much larger amount of food is required than is the case with the normal dog. Paton (5) found that splenectomy in dogs caused no essential difference in the nitrogen and salt metabolism.

Mendel and Jackson (6) detected no change in the purin metabolism following splenectomy in dogs and cats. Verzar (7) found no change in the respiratory gas exchange following splenectomy in dogs, and Karenchevski (8) found that splenectomy in dogs had no effect on the gaseous and nitrogen metabolism. Austin and Ringer (9) found that in dogs splenectomy did not in any way modify the course of the glycosuria caused by phlorhizin.

Pearce (10) and his coworkers state that the spleen exerts no constant and important influence on metabolism and that the removal of the spleen in dogs is not followed by any disturbance of the nitrogen metabolism, fat utilization or iron elimination. They also found that splenectomy had no effect on the blood lipins.

Soper (11) found that the removal of the spleen in rabbits caused a gradual and a marked increase in the cholesterol of the blood. Samuley (12) in dogs rendered anemic by pyrodin found no essential changes in the protein metabolism.

Asher and Vogel (13) thought that splenectomy influenced the iron metabolism. In relation to the iron metabolism, Schmidt (14) taught that the liver is the depot for the iron from the food and that the spleen is the depot for the iron tissues and erythrocyte catabolism. The absence of the spleen therefore interfered with the utilization of the iron by the organism and led to an increased excretion.

King (14b) found that removal of the spleen in dogs was followed by little change in the metabolic processes. He found an increase in the fats and cholesterol of the blood, with an increased absorption of fats and an increased elimination of fatty acids. There was also an increased excretion of calcium and a slight increase in output of total nitrogen. The urea showed no constant change. The sugar of the blood was not changed nor was the assimilation limit for dextrose. The urinary chlorides were diminished. The endogenous uric acid was not changed.

METABOLISM STUDIES IN MAN BEFORE AND AFTER SPLENECTOMY.

Bayer (15) studied the iron elimination after splenectomy in a case of rupture of the spleen and in a case of Banti's disease. He found an increased output of iron after splenectomy in a case of the ruptured spleen which later returned to normal. In the case of Banti's disease no change in the iron elimination was found after splenectomy.

Roth (16) studied the iron elimination in a case where the spleen was removed three years before on account of hemolytic jaundice and splenomegaly, and in a case where the spleen was removed one month before on account of rupture. He found that on both high and low iron diets the amount of iron absorbed by each of these was the same, but that the output in the second case was twice that of the first. He concluded that splenectomy in hemolytic anemias is followed by a reduction in the elimination of uric acid, iron, and of urobilin, showing that there exists a decreased destruction of tissue and blood elements.

Pepper and Austin (17) report their findings in a study of the metabolism before and after splenectomy in pernicious anemia. They found that a positive nitrogen balance before splenectomy was followed by a positive retention, fourteen days after operation, and a return to the preoperative balance after one month. The uric acid output never above normal showed a decrease of twenty-two per cent. postoperative. The output of iron in the feces never above normal decreased forty per cent. postoperative. The excretion of urobilin and urobilinogen in feces before splenectomy was three times the normal. Two months after the operation the output was one half of that before the splenectomy.

Umber (18) studied the metabolism in two individuals splenectomized for Banti's disease and found no marked variations in disturbance of the urinary constituents that could be attributed to the absence of the spleen. He found that after removal of the spleen it was easier to obtain nitrogen equilibrium which he attributed to a preoperative pathological destruction of protein due to a toxic cause. His figures show a greater output of purins before splenectomy than after.

Grosser and Schaub (19) have failed to find an increased destruction of protein in Banti's disease. Luce (20), Müller (21), and Lommel (22) have also failed to find an increased destruction of protein in Banti's disease.

Goldschmidt, Pepper and Pears (22) studied the metabolism before and after splenectomy in congenital hemolytic jaundice. They found that a slight positive nitrogen balance before splenectomy was followed by a positive retention eight days after the operation. The uric acid was decreased forty-seven per cent. after operation. Directly after operation a change in partition of creatinin and creatin occurred, but the total creatinin was unchanged. In the other urinary nitrogen constituents no change was found. No changes in hydrogen ions concentration occurred. The utilization of nitrogen at all times and the fat metabolism were normal. They found a large loss of iron through feces before splenectomy was followed by a forty per cent. decrease after the operation. The urobilin and urobilinogen in feces, after operation, was only one ninth as much as before the operation.

Tileston and Griffin (24) studied the total nitrogen, urea nitrogen, ammonia nitrogen, creatin, and creatinin in a case of chronic family hemolytic jaundice for a period of three days. On a creatin and purin free diet they found that the creatinin and urea values were normal, those for ammonia somewhat high. They found 0.06 gm. of creatin in the urine a day and found the endogenous uric acid increased. They found that tests for ailmentary glycosuria and levulosuria were negative or inconclusive. Minkowski (25) mentions that in a case of family hemolytic jaundice, Haal found an increased excretion of uric acid and a decided increase in the urinary iron.

Umber (26) found a toxigenic decomposition of protein in a case of Banti's disease. He did not think it was due to the anemia present, but since the protein destruction disappeared after removal of the spleen, he thought it was due to a toxic agent produced in the spleen. He concluded that this toxic substance not only produced anemia, but also affected the general metabolism of the organism. In another case with similar clinical symptoms, Umber found a retention of nitrogen and periodic variations in the excretion of the urinary purin nitrogen. Halpern (27), in a case of splenic anemia, found that the average purin nitrogen excretion, on a purin free diet, for a period of three days was 0.253 gm.

McPhedran and Orr (28), in a case of congenital hemolytic jaundice with splenomegaly, found six times as much urobilin in the feces as in the stool of a normal control. Möller (29) found also that the total urobilin excretion in the urine and feces is greatly increased in hemolytic jaundice. The decreased urobilin excretion after splenectomy is considered as indicative of the checking of the hemolysis and as justifying a favorable prognosis. This is particularly true of congenital hemolytic jaundice. In regard to its value in cases of splenectomy for pernicious anemia, the observations are contradictory.

Minot (30) reported studies on the nitrogen metabolism before and after splenectomy in a case of pernicious anemia. He determined the nitrogen of the urine and the feces and the urea and ammonia in the urine. He found a change from a slight negative to a slight positive nitrogen balance and an increase in percentage of urea after the splenectomy.

Lo Monaco (31) found no change in the uric acid elimination after splenectomy. Mendel and Gibson (32) studied the nitrogen, uric acid, urea, ammonia, and mineral metabolism after splenectomy in a man suffering with splenomegaly, secondary to malaria and secondary anemia. They found no striking variations. Moraczewski (33) studied the nitrogen and mineral metabolism after splenectomy for malaria splenomegaly and found no important changes. Rosenqvist (34) found in pernicious anemia and in bothriocephalus anemia variations in the nitrogen metabolism with periods of increased and decreased elimination. He thinks these conditions are accompanied by a toxigenic protein decomposition. Von Noorden (35) opposes this view and thinks the protein variations are due to the renal and alimentary changes that accompany the anemia.

Halpern (36), in a study of one case of pernicious anemia and one of splenic anemia, found normal values for the various urinary constituents. Rosenbloom and McKelvy (37) studied the metabolism in a case of congenital hemolytic jaundice with splenomegaly for a period of five days. They found a loss of 4.06 gm. nitrogen and a normal urinary nitrogen partition with the exception of the uric acid nitrogen which was increased. The nitrogen absorption was normal. They found a loss of 1.88 gm. of sulphur and a normal sulphur partition with occasional increased ethereal sulphates. They found a loss of 0.482 gm. of calcium oxide and 0.924 gm. of magnesium oxide. There was a retention of phosphates (0.07 gm.), while the amounts of earthy phosphates and total phosphates of the urine was normal. There was a loss of 0.1199 gm. of iron, with marked increased amounts of iron excreted in the urine and feces. The fat metabolism was normal, with an absorption of ninety-one per cent. of the ingested fat. The amounts of neutral fat, fatty acids and soaps in the stool were normal. Urobilin and urobilinogen were present in the urine and feces.

Denis (37b) found that splenectomy in anemia produced no change in the blood fat. Abelous and Soula (37c) think that the spleen is the place where the blood cholesterol is produced. Minot (37d) found after splenectomy in a case of pernicious anemia a disappearance of urobilinogen from the urine, a more favorable nitrogen balance and a rise in the per cent. of urea nitrogen of the urine.

Rosenbloom and McKelvy (38) studied the cholesterol metabolism in a case of congenital hemolytic jaundice and found a large loss of cholesterol from the body and they believe that this may be the cause of the lessened resistance of the red blood cells present in this disease. Medak (39) reports the following results obtained in a study of the cholesterol and cholesterol esters of the blood in certain diseases of interest in relation to diseases of the spleen:

Disease	*Free cholesterol in 1000 c.c. of blood gm.*	*Combined cholesterol in 1000 c.c. of blood gm.*	*Total cholesterol in 1000 c.c. of blood gm.*
Banti's disease before splenectomy	0.9736	0.3480	1.3216
Banti's disease after splenectomy	1.3980	0.7356	2.1336
Banti's disease before splenectomy	0.9510	0.5470	1.4980
Banti's disease after splenectomy	1.0720	0.7140	1.7860
Hemolytic jaundice before splenectomy	0.4910	0.6330	1.1240
Hemolytic jaundice after splenectomy	0.9560	0.3400	1.3020

His results show an increase in the free cholesterol of the blood after splenectomy. King (40) has also found that after splenectomy there occurs an increase in the total fats and cholesterol in the blood. Roth (41) found no increase in the iron elimination in a case of congenital hemolytic jaundice, studied three and one half years after the removal of the spleen.

Eppinger and his coworkers (42) found in hemolytic jaundice that the maximum amount of urobilinogen in the feces was 4.0 gram, the minimum was 0.012 grams found in a case of carcinomatosis and the normal average was 0.13 gram. The large increase in hemolytic jaundice is striking.

Robertson (43) and other workers have shown that a decreased excretion of urobilin takes place after splenectomy in various diseases of the blood.

Pearce and his coworkers (44), studying the relation of the spleen to blood destruction and regeneration and to hemolytic jaundice, have shown that during the first month after splenectomy, hemoglobinuria due to hemolytic serum was not followed by jaundice, and that the red cells had an increased resistance to hemolysis, while three and one half months after and even later jaundice occasionally occurred spontaneously. They have also demonstrated that the absence of the spleen has no important influence on the elimination of hemoglobin by the kidneys or its transformation into bile pigments, or the removal of such pigments. Also that the difficulty of producing hemoglobinemia and jaundice in animals splenectomized one month or more, is due to an increase in the resistance of the red cells and this increase depends upon the corpuscles rather than the serum, and they think it is associated with anemia, caused by hemolytic serum and that it is a concomitant of the regeneration of the blood, which follows the anemia caused by the removal of the spleen.

They conclude that splenectomy in the hemolytic anemias is, as a rule, followed by a reduction in the elimination of uric acid, iron, and urobilin, changes indicative of decreased destruction of tissue and blood elements.

Eppinger (45) studied the nitrogen metabolism in two cases of hemolytic jaundice, before and after splenectomy, one case of the acquired and one case of the congenital type, and concluded as follows: *"Wir kommen somit zu der überzeugung, dass mauche Fälle von hämolytischen Ikterus einen gesteigerten Stoffwechsel beigen doch von einer typischen Erscheinung lasst sich hier nicht sprechen."*

In the following tables are his data:

CASE I.

	Before splenectomy —weight 52 Kg.			*14 Weeks after splenectomy —weight 52½ Kg.*		
	N. intake	*N. output*		*N. intake*	*N. output*	
Day	*gm.*	*Urine gm.*	*Feces gm.*	*gm.*	*Urine gm.*	*Feces gm.*
1.	15.7	14.23		15.6	13.67	
2.	15.2	13.97		15.19	12.78	
3.	15.6	14.07		15.9	12.67	
4.	15.3	13.67	15.3	15.3	12.67	
5.	15.3	13.98		15.96	12.08	17.02
6.	15.6	13.78		15.13	13.99	
7.	15.7	14.30		15.3	13.78	
8.	15.8	14.70		15.76	13.10	
Total	125.2	112.7	15.3	123.85	104.76	17.02
Balance	17.5 gm. protein loss			12.94 protein gain		

CASE II.

	Before splenectomy			*10 Weeks after splenectomy*		
	N. intake	*N. output*		*N. intake*	*N. output*	
Day	*gm.*	*Urine gm.*	*Feces gm.*	*gm.*	*Urine gm.*	*Feces gm.*
1.	12.5	11.13		12.7	10.34	
2.	11.5	10.67		11.9	10.18	
3.	11.9	10.35		12.5	10.32	
4.	12.3	10.63		12.2	11.52	
5.	12.2	11.34		12.6	10.63	
6.	12.5	11.76	12.63	12.0	9.60	12.01
7.	12.3	10.38		11.8	10.79	
8.	11.5	11.61		12.7	9.80	
Total	96.7	87.87	12.63	98.4	83.18	12.01
Balance	23.75 gm. protein loss			20.06 gm. protein gain		

In a case of congenital hemolytic jaundice (46), studied before and after splenectomy, in relation to the iron and uric acid he found the following:

	Iron in stool *Mg.*	*Uric acid in urine* *Gm. (averages)*
Before splenectomy	0.177	0.834
One month after splenectomy	0.240	0.263
Three months after splenectomy	0.210	0.364

In a case of acquired hemolytic jaundice (47) he found that the iron excretion was as follows:

	Milligrams iron in stool
Before splenectomy	0.191
One month after splenectomy	0.230
Three months after splenectomy	0.220

In two cases of acquired hemolytic jaundice (48) he reports the following study of the uric acid excretion before and after splenectomy:

Case. No. I.	*Date*	*Uric acid*	*Case. No. II.*	*Date*	*Uric acid*
	3/18	1.45		3/26	1.606
	3/19	1.70		3/27	1.701
	3/20	1.23		3/28	1.679
	3/21	1.46			
Splenectomy			Splenectomy		
	5/15	0.07			
	5/16	0.045		2/17	0.245
	5/17	0.042		4/18	0.240
	5/18	0.026		4/19	0.255

He (49) found the following values for the uric acid excretion before and after splenectomy tabulated as in this table:

Case No.	*Disease*	*Date*	*Uric acid*	*Remarks*
1.	Pernicious anemia	1/3	0.976	
	" "	1/4	0.786	
	" "	1/5	0.778	
	" "	1/6	0.802	Splenectomy 1/9
	" "	4/15	0.802	
	" "	4/16	0.057	
	" "	4/17	0.097	
	" "	4/18	0.067	
2.	" "	3/6	1.532	
	" "	3/7	1.04	
	" "	3/8	1.13	
	" "	3/9	0.97	Splenectomy
	" "	8/1	0.092	
	" "	8/2	0.120	
	" "	8/3	0.170	
	" "	8/14	0.087	
1.	Hypertrophic cirrhosis	3/26	1.606	
	" "	3/27	1.710	
	" "	3/28	1.679	
	" "	3/29	1.597	Splenectomy
	" "	4/17	0.245	
	" "	4/18	0.240	
	" "	4/19	0.253	
	" "	4/20	0.300	
2.	Hypertrophic cirrhosis	3/4	1.186	
	" "	3/5	1.107	
	" "	3/6	1.182	
	" "	3/7	1.170	
	" "	6/8	0.374	After splenectomy
	" "	6/9	0.297	
	" "	6/10	0.302	
	" "	6/11	0.291	

In a case of splenomegalic cirrhosis with jaundice (50) he found in an eight day period before splenectomy that the protein balance was positive 0.437 grams, while in an eight day period, seven weeks after splenectomy, the protein balance was 1.5 grams. In the same case he reports the following in a study of the iron and uric acid metabolism:

Before splenectomy	*Uric acid*	*Iron in urine*	*Total iron*	
	0.876	0.147	0.201	8 day period.
	1.380			
	0.937			
	0.876			
Six weeks after splenectomy	0.276	0.410	0.476	11 weeks after splenectomy.
	0.290			
	0.310			
	0.220			

In a case of hypertrophic cirrhosis of the liver (51) Eppinger found in an eight day period before splenectomy that the patient had a positive protein balance of 0.625 grams. In an eight day period two months after the splenectomy, the protein balance was positive 1.125 grams.

In the same case the following were the results obtained in a study of the iron and uric acid metabolism:

	Uric acid	*Iron in urine*	*Total iron excreted*	*Period*
Before splenectomy	0.98			
	1.376			
	0.876	0.117	0.179	7 days
	1.008			
Eleven weeks after splenectomy	0.301	0.321	0.391	6 days
	0.263			
	0.318			
	0.229			

In a case of hemolytic pernicious anemia, he obtained the following values for the iron excretion before and after splenectomy:

	Mg. Fe in stool	*Mg. total Fe.*	*Period*
Before splenectomy	0.172	0.188	6 days
Four weeks after splenectomy	0.331	0.358	7 days
Three months after splenectomy	0.276	0.301	6 days
Six months after splenectomy	0.210	0.227	6 days
Eighteen months after splenectomy	0.437	0.447	6 days

In this case he also studied the nitrogen balance before and three months after splenectomy. In eight days before splenectomy the patient lost 2.5 grams of protein and in an eight day period after splenectomy the patient had a positive protein balance of 37.625 grams.

It seems from Eppinger's studies that the removal of the spleen affects the iron and uric acid metabolism, and cases with a protein loss before splenectomy showed a protein gain after splenectomy.

The Enlarged Thymus Gland from the Viewpoint of the Laryngologist*

By L. HUBERT, M.D.,
New York.
Assistant Surgeon, Manhattan Eye, Ear and Throat Hospital; Attending Otolaryngologist, Lenox Hill Dispensary.

Enlargement of the thymus gland is of considerable interest to laryngologists on account of its assumed relation to sudden death which might occur during or after an operation on the nose and throat. Usually our attention is not directed toward such cases until after such an accident occurs. It is obvious that we should endeavor to recognize these cases before an operation is undertaken, exercising great care when there is a history of dyspnea, attacks of suffocation, and choking, or when the appearance of the patient suggests a possible status lymphaticus.

In recent years our opinion in regard to the persistence of the thymus gland has been changed. It was believed formerly that this gland increased in size up to the second year after birth, and that then it gradually diminished and disappeared more or less entirely soon after adolescence.

During the world war an opportunity presented itself to examine large numbers of healthy men who had been killed suddenly. In a considerable number of cases the thymus gland was persistent and lymphoid hyperplasia was found (1). It was therefore concluded that this gland did not disappear so rapidly as had been generally thought and that the lymphoid tissue of youth persisted well into adult life.

Today it is generally accepted that the thymus gland is an organ belonging to the period of growth and development. It reaches its greatest size at the time of puberty, then undergoes a process of involution, but does not disappear entirely during life (2). It is nevertheless true that in certain cases an abnormally large thymus gland and an unusual amount of lymphoid tissue are present, which justify us to speak of a status thymicolymphaticus.

In the last three years I had an opportunity to study six cases belonging to the status thymicolymphaticus group, which had been referred to the hospital for operation on tonsils and adenoids. In three of these cases x ray examination showed an enlargement of the thymus gland. The other three patients were suspected on account of their general appearance. They showed certain signs which have been associated with a status lymphaticus.

REPORT OF CASES.

Case I.—J. T., male, six years old, was referred to the throat clinic of Lenox Hill Hospital in May, 1921, for removal of adenoids. The chief complaint was that he could not breathe well, especially at night. He had been examined in various clinics and by private physicians, all believing that the trouble was due to adenoids. The child had had practically all the diseases of childhood—measles, German measles, whooping cough, chickenpox, pneumonia, and was subject to colds and grippe. He also had had rickets and was bowlegged, so that he had to wear a brace for nine months. He had often had attacks of fainting, when he would stop breathing and appear to be dead. When he was four years old his tonsils and adenoids were removed in one of the Board of Health stations (August 14, 1919). Following the operation he was very ill, vomited for four days, and had fever, which on one occasion, was 104° F. Three weeks after the operation he was taken to Mount Sinai Hospital, where he stayed six weeks and was treated for acute nephritis.

The difficulty in breathing persisted practically since birth. There was no improvement following the operation. On questioning the mother of the child closely I found that the trouble was not an obstruction to nasal breathing, but was a dyspnea, inspiratory in type, coming on at night or after exertion, and accompanied at times by attacks of suffocation.

Examination showed that the tonsils had been thoroughly removed, and that there was practically no adenoid tissue. The nasal septum was thickened and deviated. There was marked dullness on percussion over the manubrium sterni. Physical examination in general showed certain signs of maldevelopment, which have been associated with status lymphaticus. The upper extremities were too long, compared with the thorax. There was a marked hyperextension of the phalanges, and a falling of the plantar arches (flat feet). Teeth showed small lateral incisors as compared with the central incisors. The canine teeth were flat, instead of fanged. Examination of the urine showed it to be normal.

The diagnosis of enlarged thymus was made on the history of dyspnea and attacks of suffocation and the dullness on percussion over the thymic area. It was confirmed by the x rays. An x ray examination of the chest on May 23, 1921, at the Lenox Hill Hospital, revealed a quadrilateral shadow occupying the upper and midpart of the chest. This shadow could be separated distinctly from the heart shadow and was believed to be a thymus gland. The treatment consisted of deep x ray exposures. After a few treatments the attacks of dyspnea and suffocation were gone. At the present time there is some difficulty in nasal breathing, due to a sinusitis. There is no question that the x ray therapy was of great value. He was given about twelve such treatments.

This case shows the importance of taking a careful history and of ascertaining the exact nature of respiratory difficulty. Dyspnea and attacks of suffocation cannot be due to tonsils or adenoids. The case also shows that a patient with an enlarged thymus can be operated upon without necessarily a fatal result.

Case II.—A. K., five months old, male, was brought to the Manhattan Eye, Ear and Throat Hospital on January 4, 1923. The chief complaint was difficulty in breathing. His mother was seventeen years old, his father thirty years old, both in good health. The patient was their first child.

---

*Read, in part, and cases I, II, and III, presented before the Section of Rhinology and Laryngology, New York Academy of Medicine, January 24, 1923.

The child was delivered by Cæsarean section in the Manhattan Maternity Hospital. The present trouble started three weeks after discharge from the maternity. It was noticed that the child had difficulty in breathing, especially at night. He became blue in the face and had attacks of suffocation. These attacks occurred whenever the child cried. He had been examined a number of times in a pediatric clinic and by private physicians. A Wassermann test was taken both of the child and its parent with negative results. The underlying condition was not discovered.

When the patient was brought to the Manhattan Eye, Ear and Throat Hospital, the history the mother gave made us suspect a possible enlargement of the thymus gland. There was some dullness and a sense of resistance over the manubrium sterni. Examination of the nose and throat was practically negative. The child also showed a congenital angioma on the scalp. An x ray examination showed just above the heart shadow an area of density extending on both sides of the vertebral column, which suggested an enlarged thymus. A history of difficult breathing, associated with congenital malformations, as in this case, and a congenital angioma indicates possibly an enlarged thymus.

Case III.—H. E., eighteen months old, male, was brought to the Manhattan Eye, Ear and Throat Hospital on December 23, 1922. The chief complaint was difficulty in breathing. The mother had had six children. Four were alive and well; one died suddenly when one day old, and another was born dead on account of difficult labor after which version was performed. The child was born in Harlem Hospital. It was a very quick breech delivery, lasting only ten minutes. For several days it was difficult to get the child to breathe and it could not take the breast for two weeks. It had to be kept in an incubator, although the pregnancy lasted fully nine months. The child began to sit up when ten months old, but did not walk at eighteen months. The present complaint started when the child was born. Three or four times during the night the child awoke and had attacks of dyspnea. At a children's clinic the mother was advised to have the child's tonsils and adenoids removed. Examination revealed hypertrophied tonsils and adenoids, but their size was not sufficient to explain the dyspnea. The child also showed a hyperextension of the phalanges and a very marked hyperextension of the knee joints. The latter condition might explain why the child did not walk. X ray examination showed above the heart shadow an area of density extending on both sides of the vertebral column, suggesting the presence of a thymus gland.

These three patients represent one group of cases in which the most obvious symptom is dyspnea. It is characterized by the fact that it is paroxysmal and exaggerated by hyperextension of the head and dorsal decubitus. For this reason it is worse at night. Between the attacks the respiration may be perfectly normal. The thymus gland is enlarged in every case.

STATUS LYMPHATICUS OR STATUS HYPOPLASTICUS.

There is a second group of cases in which the most characteristic symptom, so far as we are concerned, is nasal obstruction. The patients are referred to us for operation on tonsils and adenoids. Their appearance arouses a suspicion that they might belong to what has been termed the status lymphaticus or the status hypoplasticus group. In these cases there may be very little or no enlargement of the thymus gland.

Status lymphaticus or status hypoplasticus is characterized by a hyperplasia of the lymphoid tissue and a hypoplasia of the most important organs of the body, like the heart, the aorta, and some of the glands of internal secretions, especially the adrenals, the pituitary, the genitals and the thyroid. Well marked cases of status lymphaticus are easily recognized, and readers are referred to Timme's excellent publication on this subject (3). The lesser grades of status lymphaticus, however, are easily overlooked, although if certain more or less definite signs are recognized, a diagnosis may often be established with reasonable certainty. The detection of these cases would be greatly facilitated if it were possible to demonstrate by the x rays the hypoplasia of the heart and the aorta. Ewing (4) says: "I know of no observations by the röntgen ray on the appearance of the hypoplastic heart and aorta."

In a recent lecture before the German Medical Society of the City of New York, Dr. Franz Kroedel, of Bad Nauheim, called attention to the fact that the hypoplastic heart could be demonstrated by the orthodiagraphic method. This is done by determining accurately the ratio between the heart and the lung shadows, the normal ratio being one to two. The hypoplastic aorta, however, cannot be shown by the x rays.

REPORT OF A CASE OF STATUS LYMPHATICUS.

Case IV.—I. S., male, five years old, came to the Manhattan Eye, Ear and Throat Hospital on March 19, 1921, for the removal of tonsils and adenoids. The chief complaint was nasal obstruction which had been present practically since birth. The child also complained of getting tired easily and of general weakness. Examination revealed a healthy looking boy with a large amount of adipose tissue. The skin was smooth, delicate, and a pronounced blush was present on the cheeks. The tonsils and adenoids were hypertrophied and there were enlarged lymph follicles on the base of the tongue. The glands of the neck were also somewhat enlarged. The breasts were well developed and the pelvis was of the female type. The penis and the testicles were quite small, but otherwise normal. X ray examination on March 22, 1921, showed the sella turcica to be clear, and there was a faint suspicion of the thymus gland on both sides. I advised against operation. Recently the social service department of the hospital investigated the condition of the patient, and I was informed that he was being treated from the endocrinological aspect in one of the clinics of this city and that he felt fairly well.

This case was believed to belong to the status lymphaticus group on account of the general appearance of the boy, who presented a picture of health, yet was not strong.

STATUS LYMPHATICUS IN ADULTS.

In the adult the detection of status lymphaticus is not so simple. It is due to the fact that compensation of the various endocrine glands occurs, whose secretions are supposed to be antagonistic to the thymus gland. Therefore, we must add to the clinical picture the characteristics of secondary involvement of the thyroid, pituitary and adrenal glands (5).

DIAGNOSIS OF STATUS THYMICOLYMPHATICUS.

The diagnosis of status thymicolymphaticus is made on the history, general appearance and examination of the patient, and confirmed by x rays. It is not practical to take x ray photographs of the thymus gland in all cases that need operative intervention, nor would this procedure exclude those cases of status lymphaticus in which the thymus is not enlarged. The demonstration of a hypoplastic heart by the orthodiagraphic method, if practical, in all suspicious cases, would be of great value in the diagnosis.

SUMMARY.

Two groups of cases belonging to the status thymicolymphaticus type are described. First, those in which the enlarged thymus is the most prominent feature, and in which dyspnea, especially at night, is the most outstanding symptom. Second, cases which present certain signs that have been associated with status lymphaticus, with little or no enlargement of the thymus gland, and in which nasal obstruction and general weakness are the most prominent symptoms. Attention is called to the importance of ascertaining the exact nature of the respiratory difficulty and of considering a possible status lymphaticus in all suspicious cases. If this is done, we may be spared the tragic experience of an unexpected loss of a patient on the operating table. A fatal outcome does not necessarily ensue, but all patients of this type have a low resistance and complications frequently are likely to follow.

Recent Developments in Parathyroid Therapy

By H. W. C. VINES, M.D.,
Cambridge, England,
Beit Memorial Research Fellow, Fellow of Christ's College, Cambridge, England.

Owing to the confusion which may arise in studying the literature of the parathyroid glands, it is necessary to insist at the outset on the complete differentiation between the thyroid and parathyroid organs. Morphologically, structurally and functionally there is complete separation between the two types of glands; there is no conclusive evidence that the one can ever take on the function or histological appearance of the other; their removal produces a totally different symptomatic syndrome in each case, and their chemical properties are quite unlike. On the other hand, there is quite a considerable amount of evidence to show that the biological activities of the two glands are more probably antagonistic than synergic.

With the identity of the parathyroid glands established, the determination of their function naturally follows. The accepted view at the present time is that these glands serve a dual purpose; first they have the power of removing certain toxic substances from the blood stream, and second they are the essential regulators of calcium metabolism. This dual function has been epitomized from observations on clinical and experimental tetany, a field of research which overshadows all else in the literature. The toxic substances in question have been shown to be guanidine derivatives (1, 2), either guanidine itself or the methyl compound. These substances are irritative to nerve cells, and the calcium deficiency which accompanies parathyroid tetany serves to increase the nervous irritability, since the action of calcium on nerve cells is depressant or inhibitory. Following the investigation of tetany, the application of parathyroid therapy to disease has been naturally to conditions of convulsive type. We therefore find it advocated in paralysis agitans (3), in epilepsy (4), in chorea, uremia, eclampsia and so forth, since in all these conditions convulsive symptoms are present. Uremia and eclampsia are due frankly to toxemias, while a toxic basis has been suggested in epilepsy by several authors. In the following paragraphs the relation of the parathyroid glands to toxic conditions will be considered, more especially to those states in which convulsive phenomena are absent.

The withdrawal of calcium from the circulation by increased elimination is said to lead to increased irritability of the nerve cells, but yet this is not always manifested by convulsive signs, for in diabetes calcium loss may be considerable but convulsive signs are not common. In tetany, moreover, convulsions do not occur until thirty per cent. of the normal calcium content of the serum has been lost (5). What then is the effect of lowering the calcium content of the serum to a figure between the normal and the convulsive threshold? Decrease may be of two types; it may be absolute, when the total amount of calcium in the serum is lessened, or it may be relative when the total is unchanged but when some of the calcium is bound, possibly by combining with some substance so that the complex formed is not assimilable by the tissues. In either case the effect on the somatic cells is the same; they suffer from a deficiency of calcium which they can utilize.

In two series of cases investigated by me the latter form of calcium deficiency was present. The first series was limited to cases of varicose ulcer (6), which responded readily to parathyroid therapy, but less readily to calcium injections. In the second series (7), the cases by nomenclature were varied; they comprised chronic external or internal ulcerations, chronic infections of the nose and ears, chronic rheumatism, prostatic hypertrophy, certain chronic skin affections and so forth, and in addition to the cases actually investigated I have had successful results reported in chronic colitis. In all these conditions there is one common factor, the element of chronic sepsis and chronic toxic absorption from the septic focus. By intramuscular injections of calcium chloride it was found that an improvement in the condition was obtained, running concurrently with an increase in the precipitable calcium of the serum. These results have been recently paralleled by Graves (8), who used injections of colloidal calcium, in combination with lecithin, in mental states associated with chronic sepsis. But if the calcium metabolism is at fault, it is presumably the symptom of a more fundamental condition and it is natural to turn to the parathyroid glands. Parathyroid therapy was therefore used in the cases mentioned and the effect was identical with that produced by the calcium injections, except that it was more rapid and more complete. The calcium deficiency was reduced and the local lesion healed rapidly when it could be directly observed or its symptoms abated when internally situated.

In the course of using parathyroid therapy certain suggestive phenomena occurred. Where a purulent discharge was present it tended to increase about the second week of treatment, but if free drainage was naturally obtained it then decreased and finally stopped. In one case natural drainage was absent; the case was one of chronic appendicitis which became acute about the twelfth day of parathyroid treatment and required surgical interference. In certain cases no obvious septic focus was present, but parathyroid therapy was followed by a purulent discharge, often from the nose. In several cases leucocyte counts have been carried out, and that there is an actual leucocyte increase affecting chiefly the polymorphonuclear cells, is shown in the following table.

Case I.—H. G., male, aged thirty. Had had a gunshot wound of spine five years ago resulting in a complete paralysis below the umbilicus. Two bedsores were present; general debility.

Date	*Total Leucocytes*	*Polymorphs*	*Lymphocytes*
July 6	9,000	5,130	3,150
July 11	10,000	6,720	3,090
July 13[1]	17,000	13,310	3,828
July 15	16,400	12,336	3,772
July 17	15,400	10,786	3,696
July 20	18,000	13,860	3,600
July 25	18,200	14,352	3,312
July 29[2]	16,400	12,300	3,444

[1] Parathyroid therapy begun.
[2] Bed sores practically healed.

It is probable that this factor, the increase in somatic resistance, is one of the most important indirect effects of the action of parathyroid therapy in chronic infections. Calcium injections will apparently produce the same reaction, so that it would seem that the state of chronicity in infective conditions is due to an inhibition of effective cellular response, brought about by the relative calcium lack. It is possible that the calcium is bound by the toxic products of the infecting agent, and further that the parathyroid glands are damaged by the same means so that they are unable to rectify the disturbed calcium balance; ultimately therefore the onus of faulty resistance comes to rest on the parathyroid glands. If we refer to the literature of experimental tetany many instances are given and attention is often drawn to the marked decrease in resistance to infection of the parathyroidectomized animals (9). Apart from leucocytic activity there is some evidence of a decrease in antibody formation after parathyroidectomy. Ecker and Goldblatt (10) found that in rabbits thyroidectomy had no effect on the formation of hemolysins, but after the parathyroids were removed the titre of the serum was only one fifth that of the controls.

It may appear from what has been said, that a claim is made for parathyroid substance as a panacea. This is not the case except in so far as chronic infections form the bulk of common conditions with which the doctor has to deal. Further, it is not the parathyroid substance nor the calcium which is the curative agent; it is the phagocytic leucocyte, which is stimulated to increased activity indirectly by the action of the parathyroid hormone on the calcium metabolism. It is not possible to say whether the parathyroids are actively concerned in the removal of bacterial toxins from the blood or not, but it is very probable that in conjunction with other glandular organs they are liable to damage from such substances.

Much attention has been paid in recent years to toxic absorption especially from the teeth, with the result that patients suffering from chronic conditions such as rheumatoid arthritis have had all their teeth extracted on the grounds of pyorrhea. Yet in many cases no improvement has subsequently occurred, and it seems possible that the chronic toxemia has in course of time become complicated by chronic endocrine dysfunction. Hence though the toxic absorption may be remedied by the removal of septic foci, the endocrine insufficiency is more permanent and is not affected. Since it is the aim of medicine to accelerate the curative process when once disease is established, if in any case parathyroid therapy is decided upon, the first step must be the elimination of all septic foci so far as they are accessible. The best results are obtained by using the rational methods for promoting healthy tissue metabolism, and it must be realized that parathyroid substance is in no sense a "cure," but an indirect physiological stimulant of tissue resistance, which by its influence on calcium metabolism allows the defensive mechanisms of the tissues to have free play.

In the cases treated by Dr. Grove and myself, the dose of parathyroid substance used was one tenth grain of the desiccated gland given daily by the mouth. This amount was given usually for a fortnight and then continued or decreased according to progress; in some cases it was given for six weeks and in one case daily for six months, but signs of overdose were never observed. Judging by the content of precipitable calcium in the serum, the maximum effect is obtained after about eight days' treatment, but rise in the leucocyte count may commence earlier, and as has been already stated the patient must be watched after the first week for signs of pus accumulated without drainage. The preparation used throughout the clinical experiments was that made by a reputable drug house, and it must be pointed out that there may be considerable variation in the activity of the preparations on the market. The writer has been able to standardize these commercial preparations to some degree, and the following table will indicate the variations found:

Prepared by	ACTIVITY *Desiccated Powders*	 *Finished Tabloids*
A.	100, 93 100	60, 82, 68, 84, 64, 76, 69, 78, 66
B.	66	
C.	86	
D.	66	
E.	38	
F.	56	
G.		67
H.		31
I.		60

For therapeutic purposes desiccated powders under 60 are probably of little value or finished tabloids under 50. If results with one preparation are unsatisfactory it is advisable to try two or three different preparations before discarding the treatment entirely.

In the light of what has been already said, there are certain other conditions which require mention. So much has been written about tetany that it is needless to discuss it fully here, and the reader may be referred to the detailed account and bibliography given in Barker's *Endocrinology and Metabolism,* but in regard to the more acute convulsive conditions some further remarks may be made. Uremia has been treated with parathyroid substance by Remond and Menvielle (11) and successful results have been claimed. It is interesting to note that the authors found an increase in the blood urea after thyroid therapy but a decrease after parathyroid, suggesting an antagonistic action of the two substances. This may be parallelled by Hertz's (12) case of parathyroid insufficiency in which thyroid therapy aggravated the symptoms; Berkeley (3) advocates parathyroid therapy in paralysis agitans, but considers that the thyroid does serious harm, since simple thyroid massage is sufficient to cause the patient discomfort.

In the treatment of eclampsia, Massaglia (13) and Vassale (14) have claimed good results with parathyroid therapy. Turning again to the literature, we find that tetany frequently develops in pregnant animals in whom the parathyroids have been interfered with previously to the pregnancy. Borchers (15) records an illuminating case of this type in a woman who was treated for postoperative tetany by a parathyroid graft. She became pregnant, however, and in the fourth week complained of pains in the arms and legs; in the fifth month tetany became so acute that it was necessary to terminate the pregnancy, and after that she recovered completely. The graft was obviously unable to stand the extra strain, though it was sufficiently active to keep her in good health under normal conditions. From such observations the use of parathyroid therapy in the early stages of pregnancy might be worth consideration, at least on an experimental basis.

In addition to the toxic conditions in which the calcium available for the tissues is affected, there are other states in which gross errors of calcium metabolism occur, and it is possible that the parathyroid glands are involved in these also. Broderick (16) has put forward suggestions that dental caries may have an endocrine basis, and Erdheim (17) showed that defective calcification of the enamel occurred in parathyroidectomized animals. Broderick lays stress upon the likelihood of dental caries to occur in acute infectious fevers and in pregnancy, conditions in which the writer considers that parathyroid damage may occur. Delayed union of fractures is another condition in which the calcium metabolism is involved. In man this is commonly associated with some chronic septic condition; Morel (18) notes delayed union in parathyroidectomized animals and the writer can record a case improved by parathyroid therapy and removal of septic teeth.

In considering bony changes due to errors of calcium metabolism, the controversial condition of rickets naturally occurs to me. The pathology of the condition implies defective calcification of bone, but its cause is not yet clearly defined. The prevalent theory is perhaps that it is a deficiency disease due to insufficient vitamine supply associated with unhygienic conditions of life. Apart from the calcium deficiency, there is some evidence which suggests a parathyroid involvement, possibly as a secondary condition, but one to which the calcium error is due. Rickets is one of the diseases with which tetany is associated, and Paton and Findlay (19) concluded that active rickets accelerated the effect of parathyroidectomy in animals, but that the presence of healed rachitic lesions had no such effect. Boez (20) working with young rabbits found that dried parathyroid gland given with calcium phosphate hastened the rate of calcification in the bones, an effect which was not obtained by the calcium salt alone. In human beings, Pappenheimer and Minor (21) found a very definite enlargement of the parathyroid glands, due to a multiplication of the gland cells and irrespective of the state of nutrition of the subject. Mellanby (22) has pointed out the increased susceptibility of rachitic dogs to infection, and also of the occurrence of ocular changes such as cataract; this has been frequently mentioned as occurring in parathyroidectomized animals, and in man Sainton and Paton (23) have recorded a case of parathyroid insufficiency where double cataract developed. McCarrison (24) observed intense congestion in three cases and hemorrhagic infiltration in one case in the parathyroids of monkeys fed on vitamine deficient diets, accompanied by gross lesions in the intestine. He suggests that the parathyroid changes were due to toxic absorption from the gut; the thyroid glands in these cases were not affected in a similar manner nor in similar degree, Dragstedt (25) considers that there is a relation between tetany and poisoning of intestinal origin. These facts all point to the possible involvement of the parathyroid glands in rickets, and since the error of calcium metabolism figures so largely in the condition, it is possible that parathyroid therapy might be of value.

There is thus no small amount of evidence to emphasize the fundamental importance of calcium in the economy of the living organism. Of almost equal importance will be the organs which regulate its qualitative and quantitative relationship to the tissues. The regulation of calcium metabolism is a function which has been assigned to almost all the endocrine glands in turn, but in the majority of cases the evidence is highly unsatisfactory, and while one is prepared to admit a certain indirect control through the medium of the parathyroid glands, there is no reason to suppose that any other organ has a degree of control at all comparable to that of the parathyroids. In hyperthyroidism, for instance, there is a marked calcium loss and in hypothyroid states a certain calcium retention (26). Following the suggestion that the thyroid and parathyroids are antagonistic and that the parathyroid tends to stabilize calcium metabolism, there is no need to assign a definite function of calcium control to the thyroid. In diabetes again calcium loss is considerable, and an influence on calcium metabolism by the pancreas has therefore been suggested. But parathyroidectomy tends to increase sugar elimination in diabetic dogs and thyroidectomy to decrease it; it seems therefore that the parathyroids have an inhibitory action on the excretion of sugar. Friedmann and Gottesmann (27) found that diabetic dogs were more susceptible to tetany after thyroidectomy and partial parathyroidectomy than were nondiabetic dogs; they found also that thyroidectomy checked the sugar elimination. These results seem to suggest that the remaining parathyroids in diabetic dogs were less efficient than those of nondiabetic dogs. Is it unreasonable to suppose that the parathyroids may be involved in the same toxic process as the pancreas, or at least damaged by the toxic products of imperfect sugar metabolism? There seems to be no necessity for the assumption of a calcium control by the pancreas. In connection with the relation of sugar excretion and the parathyroids, it is interesting to note that Fletcher (28) found a lowered sugar tolerance in the majority of his cases of chronic arthritis. Finally in regard to those glands associated with the processes of growth, the pituitary, the gonads and perhaps the suprarenal bodies, if the rate of growth of the somatic cells is accelerated, the demand for calcium will be increased and the parathyroid glands will respond to such demand in a physiological manner. There seems to be no reason for assigning control of calcium metabolism directly to any other gland, and there is no evidence to show that any other gland can even partially restore the disordered calcium metabolism of clinical or experimental tetany.

The present position of the parathyroid glands in medicine may be briefly summarized. From the study of tetany the regulation of calcium metabolism and the removal of guanidine derivatives from the system have been established as normal functions of these glands. The importance of the latter function is at present limited to tetany, but the regulation of calcium metabolism links up the parathyroid glands with every cell in the body. Among the normal functions of the somatic cells are the mechanisms of resistance to toxic agents, produced either by faulty metabolism or by infective processes; suggestions have been put forward to indicate how the parathyroid glands may be of assistance, through their influence on calcium metabolism, in overcoming the harmful action of such substances.[1]

Some Neurological and Therapeutic Aspects of Hypophyseal Tumors*

By IRVING H. PARDEE, M.D.,
New York,
Associate Physician to the Neurological Institute.

Since Cushing's monograph on pituitary disease in 1912, knowledge of this gland, clinical syndromes of its disturbances, and their therapy, have become enormously elaborated. The progress of the study of the endocrinous organs has been also greatly developed within this time, not only in practical clinical interpretation, but also in the experimental laboratory, notably by Cannon, Hoskins, and others. Although the study of the thyroid, because of its location and size, and its more easily studied functions has quite outstripped that of the pituitary, the latter is constantly reasserting its importance in the chain of glands.

The pituitary gland is best considered as a double organ with an intervening portion, the three portions having different functions, the anterior supposedly of importance in the sphere of metabolism, bone, tissue, and sexual growth; the posterior as a regulator of function, such as blood pressure, smooth muscle contraction, menstruation, and other functions.

Disturbances in function of this gland, therefore, can produce symptoms of any or all portions, thus introducing a variety of conditions, the most striking and easily recognized of which being those produced by tumors. The part which the pituitary plays in the psychoses, menstrual difficulties, epilepsy, feeblemindedness, headache, and in a host of other disorders, is still clouded by a mass of conflicting opinion, but the question of neoplasm has now passed into the realm of medical certainty, and in late years has been further clarified by the use of the röntgen rays.

The concomitance of acromegaly or dystrophia adiposis genitalia of Fröhlich with hypophyseal tumors is known and easily recognized, but of greater import is the fact that a large proportion of pituitary disorders produces no striking disturbance of growth or metabolism, particularly the more rapidly progressing types. The maximum symptoms in these are neurological, resulting from pressure upon surrounding structures. It is these latter types that I wish particularly to emphasize.

---

*From the Department of Neuroendocrinology, Neurological Institute, N. Y., Dr. W. Timme, Director.

What then is noteworthy about the appearance of patients suffering from such tumors? They may show, in a much or less marked degree, some of the characteristics of the above types, e. g., a heaviness of bony structure, an anomaly of hair growth, spacing of the teeth, a coarseness of feature, or, conversely, a tendency to obesity, a fine feminine tendency to growth of bone and skin, slight retardation of sexual development with undescended testicle or scrotal implantation of the penis, menstrual disorders of the socalled functional type, or a mixture or any gradation of these. Alone these are suggestive but in combination with signs of pressure in the region of the sella turcica they are diagnostic. It is therefore of considerable importance to investigate minutely such minor physical signs and anthropological markings as present themselves on observation of the patient. Certain symptoms will also suggest a metabolic pituitary disorder, but these are frequently so vague and uncertain as to be rendered difficult of interpretation.

ANATOMY.

Let us review briefly the anatomical relations which are important to an understanding of the physical signs, placing particular stress upon the less frequently noted structures. The infundibular process of the hypophysis extending down from the tuber cinereum of the midbrain has surrounding it the diaphragm sellæ which is a prolongation of the dura bridging over the pituitary fossa. Anteriorly its important relationship with the optic chiasm is generally appreciated. Below it is separated only by the dorsum sella from the sphenoidal sinuses. Laterally the cavernous sinus, the third, fourth, and sixth cranial nerves, and the ophthalmic division of the fifth, are in more or less close relationship. Above, the stalk of the hypophysis arises from the tuber cinereum, posterior to which lie the corpora mamillaria, while laterally and above is the inferior temporal (olfactory) convolution. Further posteriorly and caudad is another important and less frequently recognized relationship, namely its close apposition to the interpeduncular space. This area is formed by the tuber cinereum and corpora mamillaria anteriorly, its floor by the substantia perforata posterior, posteriorly by the recesses posterior and pons, and its lateral margins are the pedunculi cerebri which run forward diverging laterally with the optic tracts partially surrounding them.

It is of note, therefore, that there are, in close relationship to the hypophysis, portions of the brain in which disturbance of function produces characteristic localizing symptoms and signs. Some of these form syndromes which we always refer to as pituitary disease, while others belong to conditions more frequently observed as belonging to lesions elsewhere.

The occurrence of pituitary symptoms accompanying tumors above or near the sella turcica and not involving the hypophysis directly is of considerable interest. Closely related to this problem is the recent experimental work by E. Leschke (1). Roussy's work is also of great importance here. He produced destructive lesions in the hypothalamic region of the diencephalon, that area below which the hypophysis lies, and his conclusions were as follows: "Alteration in the function of the diencephalon, especially the hypothalamus, may lead to important changes in the vegetative economy, showing themselves in the form of diabetes insipidus and mellitus, dystrophia adiposogenitalis, heat regulating changes, disturbance of pupillary reaction, hydrosis, and vasomotor activity." Confirmation of his work, which, when further elaborated, will throw much light upon the possible function of those important centres, has been obtained by Bailey and Bremer (2). The occurrence of clinical syndromes heretofore referred to the pituitary gland only, due to a lesion of the interbrain, throws a new light upon the interpretation of the symptoms of hypophyseal disorders in particular, and urges a word of caution upon the too enthusiastic reception of each new endocrine symptom. Are we then to consider that there is an endocrinous vegetative centre in the diencephalon or thalamic (subcortical) area whose structure, because we know it is not glandular, may be connected thereto through a sympathetic nervous chain extending into the midbrain or cortex? This has been suggested before and seems to be of considerable theoretical importance.

Upon the basis of these anatomical relationships the following neurological syndromes are found accompanying enlargement of the pituitary gland.

Anterior enlargement will cause pressure upon the optic chiasm with the familiar optic neuritis, optic atrophy, or a bitemporal hemianopsia, from interference with the fibres crossing at the posterior part of the chiasm.

Lateral pressure may involve some of the oculomotor nerves, resulting in strabismus, ptosis, or ophthalmoplegia and cavernous sinus pressure may cause an exophthalmos.

Pressure above upon the tuber cinereum and corpora mamillaria has not been productive of any reported typical syndrome in spire of the olfactory and gustatory function of these portions of the midbrain. It is close to the hypothalamic area, however, upon which the experimental lesions have been performed as pointed out above, and which has resulted in unusual pseudopituitary syndromes. Further pressure above might result in obstruction of the aqueduct of Sylvius with the development of an internal hydrocephalus and its accompanying symptomatology of headache, vomiting and papilledema.

The occurrence of socalled uncinate fits from upward and lateral pressure on the pituitary has for some time meant to us involvement of the inferior temporal lobe.

Should the pituitary enlarge posteriorly, the interpeduncular space will be involved and pressure upon one or both of the crura cerebri will occur with the resultant clinical picture of a contralateral hemiplegia or quadraplegia. Exaggeration of the reflexes, clonus, and plantar extensor (Babinski, Chaddock, etc.) responses will be obtained. This latter syndrome as part of the picture of a hypophyseal growth has seldom been noted, but in our clinic it has been brought to our attention a number of times. Cushing mentions that in large sella tumors there may occur spasticity, either bilateral or unilateral, from pressure upon the cerebral peduncles. In view of the rarity of this syndrome a case in point is reported.

A discussion of the anatomical and pathological status of the hypophysis is not complete without considering the sella turcica. In a previous paper, I have presented certain features of this problem, and since that time several other papers have been published which show the wide variety of sellæ turcicæ found in presumably normal individuals. Granted that the average measurements of a normal sella turcica are eight by ten mm., we have then a figure for comparison. The sella may be small or large, wide open or closed, eroded or smooth, but these factors only give us an indication of the size of the fossa which the gland can or does occupy and not the functional capacity of the gland substance itself. We know that the size of the thyroid is no indication of its thyroxin or iodine content, for a huge goitre may be seen with myxedema, or a normal sized thyroid with a hyperthyroidism; so also with the pituitary. Size is no criterion of its functional capacity, and acromegalic characteristics may be found with a normal sized sella, and hypopituitary symptoms with a huge fossa.

However, the evidence as obtained from radiographs of the sella turcica as to the status of the pituitary gland, though really not comparable, is of equal, if not greater importance, than that of basal metabolism determinations in thyroid disease. In pituitary growths the x ray is of course practically diagnostic inasmuch as intrasellar pressure will produce erosion or destruction of the clinoid processes and floor of the dorsum sellæ, the extent and direction of the enlargement being readily determined by the outlines of the pituitary fossa.

I should like to mention briefly an unusual type of case presenting signs of a neoplasm of the pituitary in which a normal sella turcica was found. These are in the main suprasella tumors, and their metabolic and structural changes are perhaps due to a functional disturbance of the hypophysis from regional pressure.

A stimulation of interest in the pituitary gland by the medical profession will result I hope in the more frequent examination of the sella turcica by the x ray and therefore a greater accuracy will be developed in the realm of hypophyseal diagnosis.

THERAPY.

It is not within the scope of this paper to undertake a discussion of the surgical treatment of sella tumors or the relative advantages of the transfrontal over the transsphenoidal route of approach; however, it is my feeling that the medical treatment might be stressed, and some points in particular brought to your attention which were determined at our clinic.

If I may be permitted to return to my analogy with thyroid disease, I should like to emphasize that medicinal methods of therapy, often of such satisfactory benefit to the hyperthyroid, are also most encouraging in pituitary enlargements, and should be stressed to their utmost possibilities before surgical treatment is attempted.

A careful observation must be maintained upon the visual fields and optic discs during the course of any medical treatment, and a retrogression indicating too great an increase in intracranial pressure or too great a pressure upon the optic chiasm, I consider the indications for operative measures.

It has been the impression of those interested in this field that, aside from neoplastic conditions involving the hypophysis, pituitary tumors do not arise *de novo*, but are enlargements of the gland of a functional type, chiefly hyperplasias or benign adenomata. This pathological state of the organ is usually due to a break in the complicated chain of internal secretory glands with deficiencies in the adrenals, gonads, and other glands, resulting in an attempt at compensation by an overactive pituitary body.

It then is rational therapy to give to the patient that gland which represents this deficiency and, in addition, pituitary substance itself, on the basis of supplying to the body metabolism sufficient pituitary from without thus making less demand upon the hypophysis itself. That this is borne out by facts is seen by the rapid amelioration of pituitary headaches upon administration of pituitary gland substance.

There are certain pituitary tumors which do not respond to oral administration of the gland. In these hypodermic injections of pituitrin (3), five to fifteen minims three times a week are often of avail. We have had one acromegalic patient in whom there was an incurable and inoperable pituitary growth whose only relief, even though temporary, was afforded by intravenous injections of pituitrin in saline. Pituitrin injection can therefore be considered an asset to our armamentarium in treating these hypophyseal disorders which, combined with the oral administration, seem to give the maximum therapeutic effect.

Before concluding the discussion of the treatment of this condition, brief mention should be made of the recent advances here and in France in radiotherapeutic methods. X ray application to the pituitary gland has been attempted with success both by the nasal and frontal route and the insertion of a small tube of radium in the gland substance through the sphenoidal sinus has been accomplished which, with improved technic, promises a large field of usefulness.

CASE REPORT.

For the sake of clarity one case report will serve to emphasize some of the more important points brought out in this paper. The patient has been under observation at our clinic and in the hospital for a period of almost four years. The case was reported before previous to the most interesting development and at that time was classified by Timme (4) as a case of subinvoluted thymus with an overactive pituitary from an attempt at compensation. The manner in which this compensation became pathological during a period of remission from treatment with consequent development of a tumor will be seen by the case history:

CASE.—Male, twenty-two (4). Six feet, three and a half inches in height, single, stenographer. Came to the Neurological Institute complaining of loss of memory and lack of sleep, feeling stuporous and extremely fatigued. Had had fainting attacks and headache, intratemporal in location. Was not able to do much manual work on this account and hence took a position as stenographer. Was exempt from military service, being the sole support of his mother.

While a child he was never strong. A long time was required for development, and on account of his feminine ways—was known as "sissy" to his playmates. He realized this appellation to be more or less just. He would cry easily if deprived of his way, and still does. Was always a bedwetter, and this weakness persisted to his nineteenth year. Realizing his feminine attributes, he endeavored to compensate for them by indulging in the most manly sports—boxing and football. But he was too slow to amount to anything there. He gave up the conflict and sank to his own recognized level—became a stenographer. He began to get headaches at seventeen years of age, at which time his excessive growth started.

Examination disclosed a man powerfully built. No hair on face or body except the pubic region, where it was of feminine distribution. The scrotum was divided above the penis into typical labial folds. He shaved once in two weeks. His pugnacious appearance was not borne out by his mental attitude. He cried when questioned about the simplest difficulties. His blood pressure was 100 systolic. He had the white line reaction of the skin, and his blood sugar was low. The x ray of the skull showed a sella in which erosion of the anterior clinoid was evident, and an excavation of the posterior portion of the floor. The x ray of the thorax showed a possible enlargement and persistence of the thymus. Neurological examination was negative.

The early history is that of a thymus state. The further progress, especially the headache, concomitant with the growth is suggestive of pituitary enlargement. This was partly borne out by the picture of the sella. His headaches became less frequent than they were, but his fatigability was marked. His growth seemed to have ceased. This case belongs to the third stage of the thymic adrenal-pituitary syndrome of Timme—with the giantism gradually reaching its acme, and the stuporous and drowsy mental condition of a dyspituitaric still present, with great fatigability, low blood pressure, and low blood sugar content. The enlargement of the sella turcica, however, gave promise of a gradual efficient compensation taking place. Feeding of whole gland pituitary extract within two weeks measurably improved his symptoms.

On a second admission to the hospital two years and three months later, he complained of dizziness, intratemporal headaches, nausea, vomiting, and staggering gait.

Physical examination revealed, height six feet, two inches, 7¾ hat, 15¾ collar, 11 shoe; he shaved twice a week; swaying station and unsteady gait, no change in reflexes.

On September 13, 1921, ophthalmoscopic examination by Dr. Ward Holden showed mobility, with fields and fundi normal. Blood pressure 96. Sugar curve .1 per cent., .14 per cent, and .125 per cent. Urine was negative. Wassermann test was negative. Treatment: Pituitary, half a grain, three times a day, after meals.

Although he was told to return once a week for observation, he disappeared for two months and then went to St. Luke's Hospital, where I saw him again. The examination revealed hyperactive knee jerks and Romberg present. Fundi showed bilateral edema of nasal half of each disc. The Wassermann test was negative. X ray by Dr. L. T. LeWald reported that the pituitary fossa was markedly enlarged both in anteroposterior and vertical diameters. There was erosion of posterior clinoid process.

He was referred back to the Neurological Institute where examination showed the following: Eyes, nystagmus to right and left; mobility normal; fields complete, dics showing moderate edema of nasal half of them (Dr. Holden). There was tremor of tongue, spasticity throughout, gait spastic and unsteady, no Romberg, ataxia, or asynergia. Reflexes: Arms, present, exaggerated, Klippel-Weil present, epigastrics and abdominals present and equal, cremasterics and bulbocavernosus lost, knee jerks exaggerated, tendency to ankle clonus and plantar extensor response obtained. Laboratory reports: Blood count normal, spinal fluid showed negative serology, sugar curve, .05 per cent., .095 per cent., .08 per cent.

On November 25, 1921, no headache or dizziness was reported; spasticity and papilledema unchanged. Treatment consisted of pituitrin, seven minims hypodermically every second day and varying quantities of pituitary by mouth.

The patient was discharged a month later with exaggerated reflexes and slight haziness of outline of nasal half of discs. He felt quite well. He was instructed to continue pituitrin injections, q. o. u., and take pituitary, one grain, by water, and report once a week. The patient disappeared and when again seen four months later he gave the following report. The medication had been followed out persistently and continuously and he was now entirely free from symptoms. He had no headache, dizziness, nausea, or spasticity of gait. The physical examination revealed normal visual fields and fundi; the papilledema had gone. Knee jerks and ankle jerks were not overactive, and there was absence of clonus, Babinski and Klippel-Weil.

Since that time he has been observed once in two weeks, and his status continues to improve.

We had the incipiency of a pituitary neoplasm presenting itself with a typical neurasthenic attitude and with vague complaints, doubts, and apparent psychoneurotic manifestations, but through all an undoubted symptomatology indicating an active polyglandular disorder. Under treatment he showed satisfactory improvement, losing his headache, growing hair, and bringing about a better adjustment. Then he disappeared, and on reappearing months after he showed moderate papilledema and evidence of spasticity of the legs, bilateral Babinski, and an enlarged sella turcica with marked erosion of the posterior clinoid process. Under hypodermatic injection of pituitrin combined with the oral administration, there was complete subsidence of the headache, and progressive improvement of his choked disc. After another disappearance for four months, during which time he took the treatment as outlined, he returned minus symptoms, minus papilledema, minus exaggerated reflexes, in which state he has remained for more than six months. He is now returning to work, and if his desired occupation, namely that of a policeman, is any indication of the amount of recovery from his former effeminate habits, we can feel quite satisfied with his progress.

This case presents persistent thymus with attempts at compensation by the pituitary. The latter became so pathological that an adenomatous or hyperplastic glandular mass formed of such proportion that it eroded and enlarged the sella turcica, especially posteriorly, and pressed upon the cerebral peduncles causing spastic gait and exaggerated reflexes. In addition there was general increased intracranial pressure with papilledema as a manifestation of this. Oral pituitary feeding did not produce much abatement of symptoms, but hypodermic pituitary did so to such a degree that he is now entirely free from his intracranial signs and symptoms.

CONCLUSIONS.

The intimate and important keystone position which the hypophysis occupies in the cranial cavity and its close relationship to easily localized structures in and about the interpeduncular space, make the presence of a tumor noticeable because of the pressure symptoms it produces.

In spite of the general belief that pituitary tumors must have visual disturbances, some of the largest observed on autopsy have shown none of these, and one can easily conceive of a growth enlarging either laterally or posteriorly which will completely avoid the optic nerves. Posterior enlargement of the pituitary will result in signs of pressure upon the pyramids with exaggeration of reflexes, extensor plantar responses, and spasticity.

X ray examination of the pituitary region is of prime importance in the diagnosis of disorders of that gland and the increased observation of sella turcica radiographs will show a proportionate increase in the diagnosis of hypophyseal disease, especially tumors.

The case reported in full as representative of a type of pituitary enlargement producing increased intracranial pressure and bilateral interference with pyramidal function has cleared up under treatment.

The treatment urged which is most likely to produce the maximum effect in hypophyseal tumors is a combined oral and hypodermic administration of pituitary substance.

Pituitary Tumors

By FRANCIS C. GRANT, M.D.,
Philadelphia.

In any consideration of conditions involving the hypophysis, the anatomical position, embryological origin and histological structure of the gland must be fully understood. The pituitary body, closely surrounded by a sheath of dura and connective tissue, lies deep in the recess of the sella turcica on the base of the skull. This cavity is roofed in by a dural sheath, the diaphragma sella, which is attached to the anterior and posterior clinoid processes. Through this sheath passes the infundibular stalk connecting the posterior lobe of the pituitary to the tuber cinereum and brain. Any expansion of the gland is therefore but slightly limited above and laterally, but meets bony resistance below.

Embryologically the anterior portion of the organ is derived from an invagination of oral ectoderm. Rathke's pouch, a connective tissue septum containing a multilocular cleft and lying between the anterior and posterior lobes of the gland, is a remnant of this invagination. In the tissues lying between the pharyngeal mucosa and the base of the sella, careful histological examination has shown the presence of a residue of squamous epithelium, and even of areas of glandular tissue closely resembling in structure the anterior lobe. Leegard (1) has recently demonstrated a retropharyngeal tumor made up of tissue similar in structure to the anterior lobe of the pituitary. From these epithelial and glandular rests (accessory hypophyses) tumors and cysts may arise, and it is suspected that the glandular tissue by hyperfunction may set up a clinical syndrome closely resembling pituitary disease. The posterior lobe or pars nervosa is formed by an extension downwards of glial tissue from the floor of the third ventricle and the tuber cinereum. The stalk of the pituitary is a thin strand of nervous tissue connecting the posterior lobe to the base of the brain. The stalk carries down with it the infundibulum, a continuation downwards of the third ventricle, and the blood supply to the anterior lobe. The blood supply to the posterior lobe leads directly into it by three small twigs from the internal carotid artery. The posterior lobe and stalk are surrounded by a thin epithelial layer which is continuous with and derived from the sheath of the anterior lobe. This epithelial capsule is particularly well developed where it lies between the anterior and posterior lobes. Its structure is so definite and its epithelial cells give such plain evidence of physiological action that this area is designated the pars intermedia.

The histology of the pituitary is difficult, the exact significance of many of the details brought out by various staining reactions still under dispute. The structure of the anterior lobe is relatively simple, columns of cells supported by definite fibrous tissue trabeculations and surrounded by large sinusoidal spaces into which the numerous arterioles supplying the gland freely empty. Flesch (2) and Dostojewsky (3) showed that there were two main types of these cells, chromophile and chromophobe, in this lobe. Schoneman (4) divided the chromophile type into acidophile and basophile cells, according to their staining reaction. As a result of his investigations Benda (5) considered these two cell types to be transitionals from the same parent cell. Scaffidi (6) asserted that they were separate and distinct in origin. Kraus (7), on the basis of a careful study, distinguished between granular (basophilic, eosinophilic and pregnancy cells) and nongranular cells, transitional cells, nerve cells and cells which have lost their granules. He believed that the eosinophilic variety develops directly from the reserve cells, while the basophiles spring from these same cells but may have larger nongranular homologues in the pars intermedia as an intermediate stage. The work of Bailey (8) is in accord with Kraus's findings. Apparently the cell types change with the growth of the individual; chromophobe cells predominate in the fetus; the chromophile cells gradually increase in number and at middle age are equal in number to the chromophobe. Even as to the position of the cells throughout the gland structure observers differ. Cushing (9) says that "the acidophiles are as a rule more abundant in the center of the gland, where they tend to line the sinuses; the basophiles occupy the periphery." Tilney (10) on the other hand states "that a large triangular area situated dorso superiorly is made up almost exclusively of acidophilic cells, while an even larger area situated below and to the front comprises quite as exclusively the basophilic elements. In addition to this discreet distribution, a narrow band of basophilic cells encircles the entire glandular portion, becoming somewhat attenuated as it passes beneath the acidophilic area. The bloodvessels are especially numerous in the areas where acidophilic cells predominate. Colloid masses are particularly numerous in basophilic areas, especially in apparent acini in peripheral and central zones." Lewis (11) observed granules in the cells most markedly on the side towards the blood sinus, a finding common in glands of internal secretion.

Of the structure of the pars intermedia Ewing (12) says "the cells lie in small groups surrounded by connective tissue. Often they form alveoli of cubical or cylindrical cells surrounding colloid globules and have a close relation to the blood vessels. The cytoplasm is clear, chromophobic, and lacking in specific granules."

The pars nervosa consists of a loosely placed meshwork of neuroglia cells. Roughly their fibres radiate towards the infundibulum. The histological structure of this area offers no bases of explanation for the well known physiological properties of solutions of this lobe of the gland. Dandy (13) has demonstrated sympathetic nerve fibres running down the infundibulum. These fibres may be secretory in function; and cellular detail which our staining methods cannot bring out might suggest an explanation for the physiological action.

From even this inadequate outline of the normal histology of the pituitary, the fact may be grasped that possibilities for pathological development are many and their diagnosis difficult. Even more difficult is it to connect the clinical picture with the microscopic findings over a series of cases. Four facts stand out predominantly. Pathological changes in the anterior lobe lead to changes in the bone skeleton, gigantism or dwarfism; involvement of the posterior lobe produces increased sugar tolerance and decreased basal metabolism or Fröhlich's syndrome of increased fat deposit, infantilism, metabolic and blood pressure disturbances. Diabetes insipidus is also seen. Combinations of anterior and posterior lobe symptoms may be noted. Lastly, pituitary lesions may be present which can be diagnosed by x ray or visual field changes alone without any of the symptoms usually attributable to pituitary pathology being present.

Hyperplasia of the anterior lobe of the pituitary occurs physiologically during pregnancy, and persists for some time after delivery. Subsequent pregnancies produce an increasingly pronounced hyperplasia. As the work of Erdheim and Stumme (14) showed, this functional hyperplasia affects the chromophobe cells. These cells multiply by mitosis, form large solid groups with fine granules in the cytoplasm and may progress to the formation of multiple focal adenomata. The acidophile elements are pushed away from the sinusoidal spaces which they normally tend to line and no longer dominate the picture. It may be many months after gestation before the acidophile cells regain their numerical preponderance in the field. The gestational hyperplasias may become sufficiently large to cause neighborhood symptoms, visual defects and changes in the size and shape of the sella. Infectious diseases and endocrine disturbances may cause such hyperplasias. Such for example was the case of cretinism and myxedema reported by Eichhorst (15) with hyperemia and hyperplasia of the anterior lobe of the pituitary followed by atrophy, connective tissue overgrowth with cyst formation and shrinkage of the gland. What are apparently gestational hyperplasias have been reported consisting of chromophilic elements. As a general rule chromophobe struma of the anterior lobe is not connected with the clinical picture of acromegaly, but produces neighborhood pressure symptoms without marked endocrine disturbance. Complete or almost complete destruction of the anterior lobe by gumma or tubercle is not connected with any marked hormonic syndrome, certainly with no acromegalic features. Von Monakow (16) recently reports a case of destruction of practically all the pituitary except the posterior lobe. The pathogenesis of the lesion was not clear. Clinically the case presented an atypical Fröhlich's syndrome plus marked mental apathy and a great decrease in the urinary output. Fahr (17) reports a case of almost complete replacement of the anterior lobe of the pituitary by fibrous tissue. Posterior lobe showed no changes. A clinical picture resembling Addison's disease was produced. Simmonds (18) reports four cases of myexdema in which the only pathological finding was complete destruction of anterior lobe of hypophysis by fibrosis.

Eosinophilic hyperplasias on the other hand do seem to be very definitely connected with acromegalic change. In carefully studied cases the evidence favoring this clinicopathological picture is convincing. To be sure, cases can be produced controverting this statement. For example, the case of Yamada (19), where acromegaly existed without pituitary pathology, the cases of Cagnetto (20) and Zak (21), where an enormous eosinophilic increase occurred without acromegaly, and the recent series reported by Bailey (8), where the patients whose glands showed the greatest eosinophilic hyperplasia had few clinical signs of acromegaly, and a definitely acromegalic case showed no eosinophilic hyperplasia on microscopic examination. When one remembers, however, the grouping of the cellular elements in certain areas of the gland, that these studies are made for the most part from fragments of the gland removed surgically and also the fact that the accessory or pharyngeal hypophysis may hyperfunction and cause hyperpituitary symptoms in the absence of any manifest change in the pituitary itself the reasons for the failure of the clinical and histopathological picture to coincide in every case becomes more clear.

Apparently it is not possible, by microscopic examination of a specimen from an hyperplastic gland, to determine positively whether the hyperplasia is still an active process or whether it has reached its full extent and is receding. This is of course important from a prognostic point of view. In a study of the cellular mitochondria Bailey (8) could not determine any relation between the numbers seen and the degree of hypersecretion of the gland. The more acute cases of pituitary disturbance seemed to show more mitochondria in the cells, but he could not establish any conception of the degree of hypersecretion from their presence.

While chromophobe and eosinophile hyperplasia of the pituitary are common, basophile or mixed basophile and eosinophile hyperplasia are very rare. The possibilities of error in diagnosing pituitary hyperplasia are many. Benda (22) in examining different areas in a case believed to be simple hyperplasia reported fields resembling typical adenoma, carcinoma and angio sarcoma. Myer (23) in a similar condition found areas suggesting the normal hypophysis, gliomatous tissue, sarcoma and plugs of hypophysis cells resembling carcinoma. A careful study should be made before a diagnosis of sarcoma of the pituitary is reached. Staining reactions will show the presence of granules in pituitary cells which are absent in sarcomatous tissue. A sarcoma will give rapid metastasis and show many intracellular mitotic figures. Pituitary sarcomata, when present, are almost always extrasellar growths, invading the gland from without and causing symptoms by external pressure. A majority of the tumors reported in the literature as sarcoma, angiosarcoma, adenosarcoma, spindle cell or round cell sarcoma on careful examination and staining would now be termed carcinoma. All pituitary hyperplasias can undergo adenomatous and cystic change. Carcinomatous degeneration may follow. Such glands are usually large, the capsule is ruptured, sella erosion occurs, metastases may be noted in the surrounding brain or invading the sinuses and nares. The cellular arrangement is atypical with mitotic figures, increase in vascularity and colloid material, a similar picture to that presented by carcinoma in other areas. As the tumor grows, if colloid secretion is profuse throughout, myxomatous softening, central necrosis, hemorrhage and cyst formation ensue. Calcification may occur in the cyst wall and be of important diagnostic value in the x ray findings. Gumma involving the anterior lobe alone is relatively rare. Metastatic growths apparently very infrequently involve the anterior lobe. Possibly its blood supply is so free that tumor cells do not easily lodge in it.

Tumors whose origin can be connected definitely with the pars intermedia are rare. As soon as a growth attains any size it is difficult to be certain whether it springs from this narrow band of tissue or from the adjacent lobes. The cell types composing the tumor are of little aid in determining this. Ewing (24) notes three cases. In only one, a large adenoma composed of structure resembling thyroid tissue, is a pathological diagnosis made. Weber and Schmidt (25), and Goldzieher (26) also report an adenomatous type of tumor springing from this area.

The posterior lobe of the pituitary seems to be more often involved in metastatic growths than to be the primary seat of a tumor. In a study of diabetes insipidus Mottram and Kennaway (27) collected a series of such cases. Carcinomatous metastasis to the posterior lobe alone without involvement of the remainder of the organ may follow mammary and pulmonary cancer. Melanosarcoma involving the base of the brain and posterior pituitary lobe was reported by Fleckseder (28). Few cases of tumor primarily originating from the posterior lobe are to be found. Ewing (29) quotes Bury, and Roxbury and Collis as having demonstrated gliosarcomas. Weichselbaum (30) reports two small lipomas replacing the posterior lobe.

Duffy (31) in a careful and comprehensive report of the literature, finds fifty-five cases of tumors arising from the remnants of the hypophyseal duct. Since this paper Bailey (32) has given an account of one more, making fifty-six in all. These tumors are found in the midline just behind or below the optic chiasm and usually fill and distend the sella. A connection with the infundibulum may be demonstrated in all tumors of small or moderate size. Hypophyseal duct tumors must be distinguished in the first place from cholesteatoma, and secondly, from growths springing from the choroid plexus. Erdheim (33) claimed that cholesteatoma contained keratohyalin granules while hypophyseal tumors did not. Bailey (32) claims that the latter type also contains these granules. Basal cholesteatoma and dermoids arise probably from epithelial rests carried in with the closure of the cerebral vesicles. These growths rarely lie in the midline and are often situated below the tentorium. In ependymal tumors the growth is from behind forwards through the third ventricle, and an attachment to the choroid may be noted.

Erdheim has collected thirteen cases of cholesteatoma, none of which seemed to be connected with the pituitary, and only a few were situated in the midline. Lockwood (34) has recently reported a case of midline tumor connected with the hypophysis which showed cholesteatomatous cysts and compensatory hyperplasia of the pituitary cells.

Duffy (31) classifies hypophyseal duct tumors as follows: 1. Simple papillary cyst or intracystic papilloma with intracystic cauliflower papillomatous structure. These intracystic papillary tumors are the simplest in structure and, save when they have broken through the floor of the sella by pressure, retain the simplest characteristics; the cyst wall usually shows no invasion. 2. Simpler and more complicated calcified and uncalcified adamantinomas, including the autochthonous teratoids of Ewing. These tumors show local invasion or localized carcinomatous degeneration but do not metastasize. The largest number of tumors belong in this group. 3. Group showing all the earmarks of malignant spinal cell carcinoma with extensive metastasis. These tumors are usually suprasellar and extrasellar. They are frequently accompanied by the adiposogenital syndrome and the early appearance of primary optic atrophy. The frequency of calcifications in their walls makes x ray diagnosis relatively easy.

Tumors involving the whole pituitary are fairly common. Good and Ellis (35) report an hemangioendothelioma with destruction of most of the gland. A clinical picture of myexdema was produced. Froboese (36) details the complete destruction of the entire organ by a tuberculous process. The patient died in coma. Curiously enough hypophyseal tuberculosis occurs almost always in women. Gumma of the pituitary is also seen.

From this mass of conflicting data, what facts may be deduced which will make a knowledge of the pathology determined by frozen section, immediately upon removal of the tissue, of value to the surgeon at the operating table? In the transsphenoidal approach it is important to know whether the tissue encountered is normal anterior lobe pushed forward into the operative field by a tumor behind it, or whether the tissue is hyperplasia or malignancy of the anterior lobe. If a cyst is encountered it is vital to know what the structure of its wall may be. If the tissue is normal anterior lobe the surgeon must take steps to avoid removing or damaging it. If the cyst wall contains squamous epithelial cells the operator is sure that the cyst is extraventricular and originates below the ventricle. He may puncture it without entering the ventricle. Knowledge of the type of tumor may tell us whether or not it is suprasellar and what the effect of radium will be. But it is only by careful study of these growths, a realization that sections must be cut and examined from every part of the tumor so that no area is overlooked by a search for and consideration of an actively functioning accessory hypophysis and by a closer correlation between clinical study and surgical and postmortem findings, that any progress will be made in interpreting many of the apparent contradictions which arise in an attempt to compare pathological and clinical findings.

The Endocrines in Uterine Hemorrhage

By WILLIAM LINTZ, M.D.,
Brooklyn,
Clinical Professor of Medicine, Long Island College Hospital, Physician in Chief Bikur Cholin Hospital.

INTRODUCTION.

I wish to relate my experience as an internist in the successful treatment with endocrine glands of certain types of uterine bleeding. All these cases were first carefully studied by the gynecologist and the existence of any operable condition excluded. In some of these cases the gynecologist advised operation but the patient refused. In this group of patients belong the persistent uterine bleeding at the climacterium, from the fibroid and subinvoluted uterus. Practically all of these patients were first treated by the gynecologist without relief, or in some instances would not carry out the indicated treatment; it was only then that the endocrine treatment was undertaken. The endocrines used were extracts of thymus, mammary and placenta.

RATIONALE OF TREATMENT.

In dealing with the endocrinological phases of this problem I will touch only that which is universally accepted as proved and well established. Normal menstruation is part of the phenomenon resulting from the interaction of the hormones from the ovaries, pituitary and thyroid glands. The corpus luteum is so closely associated with the rhythm of menstruation that it undoubtedly exercises an important control of this function. As long as there is an adequate and harmonious interaction of these glands the woman bleeds from the uterus, rhythmically and in a definite cycle, the bleeding being moderate in amount. However, should the ovary, the pituitary, or in certain cases the thyroid oversecrete, then metrorrhagia and menorrhagia are very likely to ensue. The thymus gland is antagonistic to the gonads, and it is only at puberty when the thymus recedes that the gonads assume their full function and menstruation begins. It is a well known fact that a persistent and active thymus inhibits the early development of the gonads, and that an early regression of the thymus favors the early function of the gonads. Conversely, hypoplastic ovaries may indicate a persistent thymus, while hyperplastic ovaries indicate a retrogressed thymus. Bleeding from the uterus is checked during pregnancy, lactation, and at the climacterium. By what process does this occur? The trophoblast, chorion, and subsequently the placenta check the uterine bleeding during pregnancy. The mammary glands acting on the uterus, ovaries, posterior lobe of the pituitary, and the related glands check uterine bleeding during lactation. The uterine contractions felt by the mother while nursing her child are too well known to need any comment. At the climacterium the gonads atrophy. The vegetative nervous system is closely connected functionally with the endocrine glands.

TYPES OF CASES.

The patients treated may be classified in five groups.

Group 1.—In this group belong married and unmarried women, as a rule young in age, who on physical examination show nothing abnormal. They complain of nothing but menorrhagia or metrorrhagia or both. However, upon questioning these patients closely, symptoms indicative of a disturbed endocrine function can invariably be elicited. Most of the cases treated belond in this group. Of the married women, some had children, others were sterile. The bleeding in some was very profuse and the duration of this condition in others was a matter of years. Yet there was nothing in the pelvis, as far as could be ascertained, to account for this condition.

Group 2.—Subinvolution of uterus as for example bleeding following curettage of the pregnant uterus without retention of fetal products.

Group 3.—The bleeding which occurs in some women at the time of the climacterium. The diagnosis made as a rule in these cases is fibrosis (?) of the uterus.

Group 4.—Cardiovascular disease with nephritis and associated with hypertension.

Group 5.—Uterine bleeding in cases showing disease of the ovary, the bleeding persisting after the removal of the pathological condition.

ILLUSTRATION OF GROUPS.

Group 1.—The women in this group all show definite endocrine disturbance, usually hyperthyroidism. Some show symptoms indicative of dysfunction of the pituitary; otherwise their history is absolutely negative.

Group 2.—Mrs. A. S. was admitted to the hospital October 8, 1921, complaining of severe and continuous uterine bleeding of one month's duration, with clots, weakness, pain in lower abdomen, fainting spells, headache and dizziness. With the exception that the patient suffered from influenza and pneumonia three years ago, her past history was negative. Shortly after her attack of influenzal pneumonia typical epileptic attacks developed, and on the day of admission to the hospital she had several attacks. On September 8th, one month prior to admission, a dilatation and curettage for the interruption of pregnancy was performed. This was the cause of the bleeding. On September 20th she was removed to a hospital, curetted, but no retained product of conception was found. She remained there for five days during which time everything possible to stop the bleeding was done, but without results. While at home large doses of morphine, ergot and pituitrin and all sorts of local treatment did not control the bleeding.

Physical examination showed a young woman poorly nourished, very sick in appearance, with extreme pallor of the skin and mucous membranes, with slight hypertrichosis of upper lip and a palpable thyroid. The heart sounds were rapid, weak, and of poor muscular quality. Everything else was negative. A gynecological examination presented a profuse uterine discharge, with an enlarged, soft, slightly tender uterus, otherwise negative. She was given by mouth mammary, placental and thymus extract, each fifteen grains three times a day. Each day the bleeding became less until on the fourth day it practically stopped and all the symptoms gradually disappeared. On the seventh day after admission she passed two large clots (old?) and stained slightly and then the bleeding stopped. She appeared remarkably well in appearance. The epileptic attacks continued for three weeks and then stopped. Pelvic examinations at different periods showed that the uterus was becoming smaller and firmer and that the tenderness was disappearing till it became normal. She was discharged perfectly cured. The treatment consisted only of the above named glands. I saw the patient three and a half months later. She was perfectly well; had had no more epileptic attacks.

Laboratory findings: Urine—chemical, cytological, Mosenthal and phenolsulphonephthalein tests were negative. The hemoglobin varied from 70 to 75 per cent. (Sahli); red blood corpuscles, 3,020,000 to 4,000,000; white blood corpuscles, 6,400 to 8,400; polymorphonuclears, 60 to 73 per cent.; lymphocytes, 27 to 40 per cent.; coagulation time on four different occasions, 4 to 5 minutes. Wassermann test was negative. Blood chemistry—sugar 0.135 per cent., creatinin 2.0 mgms., nonprotein nitrogen 27 mgms., urea 12 mgms., CO_2 50. Sputum and feces were negative. The blood clots were examined histologically repeatedly for evidence of conception or malignancy, with negative results. Blood pressure varied from 95/50 to 120/60, temperature from 99 to 100, respiration from 18 to 26, and the pulse from 70 to 85.

Group 3.—Mrs. C. M., forty-four years of age, was admitted to the hospital on August 31, 1921, complaining of severe menorrhagia, metrorrhagia, abdominal pain, headache, and weakness. Family, previous, personal, venereal, and obstetrical histories were negative. Menstruation began at fourteen, occurred regularly every twenty-eight days, lasting seven to eight days, bleeding very profuse, dark, with clots, and exceedingly painful. The present illness began on August 17, 1921; the patient flowed very profusely for seven days, the discharge being full of clots. Then she had amenorrhea for two days when bleeding reappeared even more profusely, accompanied by severe abdominal and pelvic pains. Physical examination showed a well nourished woman with a moderate anemia of skin and mucous membranes and weighing about 180 pounds. Heart, lungs, liver, spleen, kidneys and lower extremities were negative. There was a painful area over right hypochondriac region and lower abdomen. A pelvic examination revealed a tender fibrotic uterus whose cervix was lacerated and from which a profuse dark bloody discharge was flowing.

Treatment had been as follows: Hydrastis, fifteen minims, three times a day; an ampoule of pituitrin three times a day; placental extract, five grains, three times a day; ice bag to lower abdomen and packing. After five days of this treatment bleeding continued just as profusely as before. To rule out malignancy, a curettage was performed by Dr. Ralph Beach. Microscopic examination showed no malignancy. On September 14, 1921, after bleeding for nineteen days, the patient was placed on thymus, mammary and placental extract, five grains of each three times a day and all other medication stopped. Next day she bled as much as before. In the next three days the bleeding diminished until on September 30th she only spotted. On the 21st the bleeding stopped completely and did not reappear. Two months later at the time of expected menstrual period, she had a normal menstruation. Laboratory findings: Urine was negative. Blood—hemoglobin, 65 to 70 per cent.; red blood corpuscles, 3,500,000; white blood corpuscles, 14,000; polymorphonuclears, 65 per cent.; lymphocytes, 35 per cent.; coagulation time six and a half minutes. Wassermann was negative. Temperature, 99° to 99.6°; pulse, 85 to 95; respiration, 18 to 20; blood pressure, 120/60.

Group 4.—Mrs. A. S., forty years of age, was admitted to the hospital on August 22, 1921, complaining of dyspnea, orthopnea, palpitation, polyuria, nocturia, and at times dysuria, headache, dizziness, nausea and vomiting, edema of lower extremities, and nonproductive cough. Family, personal, venereal and past histories had no present bearing on the case. Menstruation began at ten years and occurred every twenty-eight days, duration eight to ten days, painless, less in amount and irregular during the last two years. She had had four children and five miscarriages. Physical examination showed a middle aged woman, with pyorrhea. Heart was enlarged to left anterior axillary line, regular, sounds of poor muscular quality, first aortic roughened and presented a soft blowing systolic, second aortic decidedly accentuated. Lungs showed signs of congestion at both lobes and edema of lower extremities. Everything else was negative. The patient had been menstruating since August 19th. Gynecological examination revealed a lacerated cervix and a moderately enlarged uterus. Temperature, pulse and respiration were normal. Blood pressure was 250/130. Laboratory findings: Urine, specific gravity 1.016; albumin, moderate amount; moderate number of hyaline and granular casts; otherwise negative. Mosenthal test, day output 500 c. c., specific gravity varying from 1.003 to 1.017; night output 700 c. c., specific gravity 1.010. Phenolsulphophthalein test, first hour four per cent., second hour sixteen per cent., total twenty per cent. Blood: hemoglobin, 75 per cent.; red blood corpuscles, 4,000,000; leucocytes, 7,000; polymorphonuclears, 77 per cent.; lymphocytes, 23 per cent. Blood chemistry, sugar 0.14 per cent., creatinin 1.5 mgms. Wassermann negative. Sputum and feces were negative.

Treatment consisted of phlebotomy, hot packs, colonic irrigation, cathartics, diuretin and digitalis. The patient improved remarkably and the blood pressure dropped to 170/100 and stayed there. Menstruation ceased on August 24th. On August 29th she began to bleed profusely day and night. Blood pressure was then 170/100. Large doses of ergot, ovarian extract and local treatments had no effect. Bleeding continued, discharge was dark and full of clots. On September 8th she was given by mouth mammary, placenta and thymus gland, ten grains three times a day. On September 9th the bleeding had somewhat diminished, and on the tenth day it was still less and there were no clots. In the next three days she was only spotting and in the following two days all spotting ceased. When discharged on September 22d there was no uterine bleeding and her general condition was greatly improved.

Group 5.—Mrs. A. B., aged fifty-six, was admitted to hospital on August 25, 1921. She had complained for the last twenty years of progressive abdominal enlargement, frequency of urination, constipation, headache, progressive weakness. For the past six months there had been severe menorrhagia and metrorrhagia with abdominal pain. The family, personal, past, venereal and obstetrical histories were negative. Menstruation began at fourteen, was regular, every twenty-eight days, moderate in amount or profuse at times, lasting six to seven days, and slight dysmenorrhea. Physical examination showed a patient weighing two hundred pounds, with marked hypertrichosis over upper lip. Heart was somewhat hypertrophied and its sound distant and faint. Lungs showed a few crepitant râles and diminished breathing over both bases. Liver was enlarged three finger breadths below the right costal region. Abdomen was very large and overhung to middle of the thighs. Over lower half of abdomen a smooth round hard mass was palpable which on percussion was dull. From the uterus there was a bloody discharge, dark and full of clots. Temperature, pulse and respiration were negative. Blood pressure was 210/100. Laboratory findings: Urine, faint trace of albumin, otherwise negative. Blood, hemoglobin, 75 per cent.; red blood corpuscles, 3,500,000; white blood corpuscles, 9,000; polymorphonuclears, 78 per cent.; lymphocytes, 22 per cent.; coagulation time five and a half minutes. Wassermann was negative.

As the bleeding was very profuse on August 30th a nine pound ovarian cyst with a twisted pedicle was removed by Dr. G. I. Miller. The operation also revealed an enlarged fibrotic uterus, a general visceroptosis and a marked diastasis recti. The blood pressure came down to 170/100 but the uterine bleeding continued just as profusely. Ergot and pituitrin in large doses were of no avail. Twenty-one days after the operation (September 20th) placental, mammary and thymus extracts, ten grains each, three times a day, were given. The next day the bleeding was just as profuse. On September 22d the bleeding lessened slightly and the clots were fewer. On the 24th the bleeding was markedly diminished. On the 25th, 26th, 27th she was only spotting, and on the 30th it stopped completely and did not reappear.

From the cases cited above we see that in this group the uterine bleeding is a purely endocrine phenomenon, that the administration of endocrine glands is physiological and rational, and that their effectiveness in this condition may be logically expected. Quite frequently in uterine bleeding it is almost impossible to point out definitely which one gland is at fault, and even if this was possible, while this malfunction may be primary in one gland—say the ovary—yet in most instances its relation to the thymus, thyroid, and pituitary is so close that the result is secondary. For this reason, as well as for the physiological nature of the problem as considered above, I deem it advisable, in the treatment of these patients, to combine the thymus, placental and mammary extracts.

GENERAL REMARKS.

It will be observed that there were earmarks of endocrine disturbance in every one of the cases illustrating the groups. Not infrequently some of these patients are hysterectomized, the x ray or radium being used. Some of these patients I have seen and watched for years. While in certain instances this treatment is very successful, in others, even if the bleeding is completely controlled, the patient suffers from the endocrine disturbance of which the bleeding is only a symptom. The uterus and ovaries are not always the primary cause of the bleeding but rather the secondary. This is illustrated by the patient representing Group 4. She began to menstruate at ten, which would indicate an early retrogression of the thymus, and had five spontaneous miscarriages, an indication of an overactive pituitary. Sometimes this treatment fails in types of cases where we have a right to expect good results. Why this is so I do not know. The dose varies with the severity of the case, ranging from five to twenty grains of each of the endocrines three times a day. It is advisable to continue the medication in smaller doses for some time after cessation of all bleeding. Are the results lasting? In some instances, yes; in others, no. A week before the expected menorrhagia give small doses of the endocrines and in some instances throughout the period of menstruation.

CONCLUSIONS.

1. The endocrines are chiefly responsible for certain types of menorrhagia and metrorrhagia.
2. Such cases are favorably influenced by the extracts of endocrine glands.
3. The thymus, placenta, and mammary organs are physiologically antagonistic to the endocrines producing uterine bleeding.
4. The combination of extracts of these three glands is more effective.
5. Surgery, x ray, and radium, though they may stop the bleeding, do not cure the patient.
6. The treatment is absolutely harmless.

1352 Carroll Street.

The Endocrines in Otolaryngology*

By SAMUEL M. WILSON, M.D.,
Philadelphia.

The subject to which I invite your attention lies in the borderland between otolaryngology and general medicine. A certain amount of general treatment is frequently necessary to assist in reducing intumescence, to cause absorption of exudates and after operations to favor healing with a minimum of scar tissue. Some of the socalled endocrines appear to help in this manner. The success of operations, or other measures which we have adopted, may depend on the action of these remedies, therefore personal supervision is necessary for their successful use. In neurotic conditions we recognize the nasal intumescence, rhinorrhea and asthmatic seizures as merely an annoying and conspicuous part of a general vicious circle in which the erectile tissue of all parts of the body is involved. Skillful treatment of the nasopharynx will give prompt relief of distant symptoms having no apparent connection with the nasopharynx. Local treatment relieves intumescence. Pressure will require resection of the septum or turbinates.

The lack of vascular tone, however, previously manifested in so many ways, is improved to only a slight degree and prevents a complete cure, no matter how thorough the local treatment may be. The condition seems to recur. The subjective symptoms continue and endocrine treatment is necessary to relieve these.

When intumescence is present pituitary extract representing from one third to one half grain of the gland, combined with an equal amount of the chloride of sodium, is an average commencing dose for an adult. It materially helps to relieve the sinus conditions secondary to engorged turbinates and the sleeplessness, headaches and mouth breathing induced by them. The administration must be continued for a considerable time.

Similarly, a hypodermic injection of six or eight minims of pituitrin and one or two of adrenalin will frequently relieve extreme hoarseness, when due to this condition and will maintain the effect for about twenty-four hours or more.

Only after a thorough shrinking with cocaine can we determine whether an obstacle exists which will require surgical removal, treatment by other means being a mere waste of time. It is evident that although the glandular treatment is mentioned as affecting curative changes in several conditions, it is only as an adjuvant to the measures commonly used when the glands are omitted. Hypodermic injection is better than administration by the mouth, two or three in the week being sufficient in most cases. The subject is such a prolific one for debate and for the expression of contradictory opinions among those who have made a scientific study of it, that an attempt to explain the underlying principles seems useless, but an important action appears to be their aid in supplying a deficiency of one or more of the salts of the mineral earths. Calcium is commonly mentioned in this connection, but it quite frequently seems that magnesium, potassium or sodium is the one required. Probably an ionization takes place, for only a small quantity is required to cause improvement.

After such an operation as a sinus exenteration healing may be slow and accompanied by excessive scar tissue. In this, thyroid therapy is worthy of trial; at first in a small dose, such as one quarter of a grain of the gland. If well borne, the dose is increased. In streptococcic pharyngitis and in the enlarged cervical glands that accompany some infections of the nasopharynx and sinuses, lymph gland in five grain doses has a satisfactory effect. Like thyroid with which it may be beneficially combined, it will in susceptible patients induce symptoms of thyroid intolerance, necessitating its temporary withdrawal. When prescribing this treatment for adenitis, it is advisable to withdraw it temporarily as soon as any diminution in the size of the swellings is noted and to substitute codliver oil. After a few days, if resolution is not proceeding too rapidly, the thyroid and lymph gland may be resumed, the oil being continued.

Treatment with lymph gland will usually cause a reduction of simple thyroid enlargement, as does treatment with thyroid gland and, as announced by

---

*Read March 15, 1922, before the Otolaryngological Section of The College of Physicians of Philadelphia.

Hugh Ashby in 1913, it will reduce to normal most cases of chronic enlargement of adenoids and tonsils, with a corresponding improvement in the health of the patient. It has been suggested that hypertrophy of tonsils and adenoids is not usually a primary pathological condition, but the effort of the system to combat such a one. Whether or not this view is entirely correct, there is reason to believe that treatment of the nasopharynx will usually lead to improvement. As is so likely to occur after a tonsillectomy, a patient who has suffered from rheumatism is apt to develop a light attack of that disorder while being treated with lymph gland.

Pituitary, given intravenously with a small dose of adrenal, is probably the most prompt, reliable and powerful stimulant of the heart and circulation at our command. It acts well in surgical shock and in influenza, the effect of a single dose may be maintained for as much as thirty-six hours.

Instead of being contraindicated in hemorrhage, it is useful in that condition, especially if the bleeding comes from an oozing surface, as during tonsillectomy or a nasal operation. Potent for good, an overdose may cause alarming symptoms, prominent among which is air hunger. Any one undertaking its administration should know this and that the symptom will subside if the patient remains recumbent and quiet. In an elderly person, it is a wise precaution to give only half the dose intravenously for a prompt effect and a few minutes later give the rest subcutaneously, a preparation containing adrenal being absorbed rather slowly from the subcutaneous tissue. A peculiar phenomenon, seen not infrequently in asthmatic patients, is the great and prompt relief that may follow a dose of adrenalin and be maintained for twenty-four hours or more, and then in the same subject, on another and apparently similar occasion, not only no relief follows, but the condition be made worse.

In a case in which hemorrhage is anticipated, for instance, after a turbinectomy in which subsequent packing is not intended or where a history indicating a tendency to abnormal bleeding has been obtained, a preliminary injection of one of the hemostatic serums will greatly lessen, or perhaps entirely avoid that outcome. The addition of one minim of adrenalin and four or five of pituitrin lessens the likelihood of the anaphylactic symptoms that sometimes follow the use of the serum. If hemorrhage has already begun, the same remedy should be used intravenously. To one who has not used it in this manner, the result is unbelievably swift. The class of patients in whom adenoid and tonsil affections are found contains a large proportion of those in whom the socalled status lymphaticus exists. Under anesthesia, no matter how skillfully induced and in some cases merely from the fright that thought of an impending operation induces, they at times come perilously near sudden death. Such accidents are not uncommon. Lowering the head will sometimes tide over the crisis, but our most potent remedy is an intravenous injection of one or two minims of adrenalin, with four or five minims of pituitrin. The jugular vein is in easy reach, and even in the excitement inseparable from such an emergency could hardly be missed. If circulation has not absolutely ceased this procedure will restore it, and even when it has apparently stopped for half a minute or so, it is stated that such an injection into the heart muscle will again induce contractions. Of this latter I have no personal knowledge.

2007 CHESTNUT STREET.

The Relation of the Endocrines to Internal Medicine*

By ARTHUR H. HOPKINS, B.S., M.D.,
Philadelphia.

The importance of the part played by the endocrine glands in internal medicine is, I believe, beyond our present realization. From the present literature, which is steadily accumulating along these lines and is revealing much that is new in this field, one's thoughts drift along into the realm of the future where one may see, though dimly as yet, great possibilities. In the consideration of our patients' symptoms, bearing the endocrines in mind, the possibilities again creep up of what might be done for them could we but have a little clearer insight into their meaning. In spite of the progress that has already been made in this field, the subject still remains a complex one, and there is much to be desired from the viewpoint of etiology, diagnosis and therapy. We know many of the etiological factors underlying the dysfunctions of these glands, but further progress must be made in this field before theory can be supplanted by fact. An attempt at a classification of these factors will be given a little later.

DIAGNOSIS.

The question of diagnosis is paramount. A heavy responsibility rests upon the shoulders of the clinician, for it is demanded of him that he not only make the diagnosis, but if he is to fulfill his function as an internist, he must go beyond this and ascertain the disturbance or condition which first called forth an increase or a decrease, or a dysfunction of one or more of the glands involved.

Here the question which confronts us all today is how best this diagnosis may be made. The clear cut cases need no description as they are familiar to us all. It is rather the atypical syndromes, suggestive but vague, which give us the most difficulty in establishing a diagnosis of sufficient accuracy as to form a sound basis for therapy. There are several ways which will be of service in such a diagnosis and these will be mentioned briefly with the hope that they will be of some assistance from the practical viewpoint.

In the first place we must familiarize ourselves thoroughly with the type of questions necessary in history taking, to elicit the points of most importance in establishing factors bearing on glandular disturbances. Many leads may be overlooked entirely by failure first to take and then properly to analyze a fairly comprehensive history. To go into the details of the points to be investigated would be to go beyond the scope of this paper. Suffice it to say that the three chief factors to be borne in mind are: First, heredity; second, body structure of the individual, and third, exciting causes leading to development of definite symptoms.

---

*Read before the Northern Medical Association of Philadelphia, February 24, 1922.

In questioning the patient concerning heredity we have to recall that, aside from the presence of anomalous body contour in the antecedents, such diseases as diabetes, goitre, hay fever, asthma, obesity, epilepsy, and periodical headaches are all to be considered. Next the general body structure of the individual has to be studied and such factors as the length of bones, condition of muscular tissues, distribution of hair, the skin, teeth spacing, etc., are all to be borne in mind.

ETIOLOGY.

Finally, as mentioned above, the discovery of the exciting cause leading to the development of symptoms indicative of the endocrinal disturbance may be of as much importance as is the recognition of the disturbance itself, and the mere administration of organ extracts to meet the apparent demands of the organism, without eliciting the underlying cause, is unsound therapy. Palliative treatment this is, and quite valuable in a tentative way, but not sound, if the condition is not traced to its basal cause.

The exciting etiological factors which seem to be most prominent, after having laid due stress on heredity and developmental defects, are as follows: Trauma, tumor, physiological epochs of life, infectious diseases, focal infections, toxemias, diet (proteid, fat and carbohydrate, idiosyncrasies, starvation), emotions, as mental strain and worry, fatigue and chilling.

Taking these up individually, little attention need be paid to the influence of tumor formation on the pituitary, thyroid, and other glands as these conditions are selfevident even to the inexperienced.

Under physiological epochs of life, the gynecologist as well as the internist must be more and more impressed with the possibilities offered by organotherapy for the relief of many formerly intractable conditions. These epochs, especially puberty, menstruation, and the menopause, are productive of many and varied disorders, owing to the disturbed equilibrium in the balance of the endocrine glands occurring at these times. The response of the premenstrual pituitary migraine to proper organotherapy and of the nausea of pregnancy to corpus luteum are sufficiently striking evidence of cause and effect in this group.

Infectious diseases have long maintained a prominent place as causative factors of disturbed endocrine function, histological changes being found in the glands of individuals who have succumbed to the infections, of which influenza has occupied a prominent place. Hyperplasia of the anterior lobe of the hypophysis has been occasioned experimentally by innoculation of rabbits with typhoid bacilli. As Cushing (1) suggests, the pituitary normally reacts to bacterial intoxications, and further, animals subjected to a partial hypophysectomy are exceedingly unresistant to infections. He maintains that the intact gland probably evolves some antagonistic substance and in so doing there is produced a functional hyperplasia. The relation of infections to the other glands is merely mentioned here in passing, as the facts are too well established to call for further comment.

FOCAL INFECTIONS

In focal infections we may have an equally potent source of disturbance of these socalled defense glands, more insidious, however, than in the case of the acute infections, probably because the introduction of toxins into the body is less rapid and less overwhelming, and we may be justified in assuming that the defense of the glands in these instances is more gradual, just as it may be less urgent. If the condition is permitted to continue its effects will probably make themselves manifest in due time.

TOXEMIAS.

With regard to toxemias and their effect upon these glands, one finds no dearth of evidence in the literature. Indeed, the relation of the gastrointestinal tract to the endocrines may be of more importance than we have been inclined to attribute to it. Lane's report of atrophy of the thyroid due to faulty intestinal absorption is only one of many instances in point. From the verbal report of a neurological colleague and from my own results in the past year I am convinced that faulty intestinal digestion and inadequate elimination, when sought for and corrected, offer results both gratifying and significant.

DIET.

Diet is another causative factor which is of considerable value from the viewpoint of therapy. The ingestion of large amounts of carbohydrates causes an increase at times in the hypophysis. Given glands which are unstable as the result of heredity or of some other influence, it does not seem to be assuming too much to say that a concentrated carbohydrate diet may readily disturb the balance of the pancreas, the pituitary, and as a consequence, the thyroid, in the course of metabolism. From the experimental side of the picture, one cannot read the works of McCarrison (2) without being tremendously impressed with the glandular changes that are produced in animals, as a result of starvation and of continued withdrawals or introductions of the various foods, not in their normal proportions. An interesting and suggestive feature that this author emphasizes is the fact that during these studies, alterations in the structure of the glands preceded, for long periods, any symptomatology. Hypertrophy of the adrenals due to deficiency of fat, atrophy of the thyroid from inanition, and hypertrophy of the thyroid with forced feeding of fats, and finally the dependence of adrenal function upon the proper balance of foods, are a few of the many convincing facts pointing to the importance of investigation into, and the correction of, faulty diet as an underlying cause of unbalance of the ductless glands.

Emotions have long been recognized as potent factors in upsetting the normal balance of the endocrines and of ushering in changes, which, in time, produce definite disease, as in the case of exophthalmic goitre. Could a better illustration of this be offered than the report of Richards and Etienne (3) who cited cases of exophthalmic goitre, with high blood pressure, developing within a period of twenty-four hours as a result of terror due to bombarding of Paris by airplanes in the course of the world war. Such instances are striking and convincing for the group in which sudden and great fright produces equally sudden and great changes in the thyroid gland. More insidious, however, and more cryptogenic because of this fact, are the great number of emotional causes in our daily life which exert their action more gradually and over a longer period of time and which are consequently more readily overlooked.

The causes of diabetes as given in textbooks, include worry and anxiety. According to Cobb (4), "this assumes that mental causes may upset a bodily function or functions and thereby disorganize metabolism. Prolonged anxiety, business worry, or a sudden shock are said to produce diabetes, just as does puncture of the floor of the fourth ventricle. It would seem equally possible that the same causes can and do upset the mechanism which governs the balance between the ductless glands."

Finally fatigue, resulting from overwork, and especially mental overwork, while regarded as a symptom in some of the endocrinal syndromes, would seem to be well placed with the group of etiological factors given above.

The discussion of the etiology of disturbances in the ductless glands has been given at some length, but the importance of a knowledge of, and a careful search for, the cause in all of these cases may be as important to the patient and the clinician as is the judicious use of organotherapy.

To turn now to some of the endocrinal disturbances that are encountered in internal medicine, I wish briefly to refer to a few which recent investigations have revealed. I shall not consider exophthalmic goitre, acromegaly, hypopitutiarism, Addison's disease, and others concerning which our impressions are comparatively well fixed, but shall discuss some of the more atypical and as yet less well defined conditions.

In this latter group may be mentioned certain types of obesity, neurasthenia, epilepsy, pituitary migraine, and certain menopausal conditions. In a former article (5) I have described one phase of the menopause as influenced by the endocrine, and in another article soon to be published, the pituitary migraine is described in connection with the presentation of a series of cases.

OBESITY.

In considering obesity an hereditary tendency is common and dietary factors are obviously important. However, "the endocrine glands stand in the first rank as directive agents of the phenomena involved in the development of this condition." Peterson and Walter (6) in a study of twelve hundred subjects, in which twenty-five hundred basal metabolism observations were made, confirm the view that basal metabolism tests are necessary for diagnosis and therapy, but they also state that the mass of evidence is against weight being influenced to any consistent degree by thyroid activity alone, as evidenced by this test. In their series they had thirty-two cases of high metabolism and low weight, nineteen of which were exophthalmic goitre. On the other hand, they had twenty-two subjects showing high metabolism and overweight, and in general with the overweight there was an excess of blood sugar.

From this great mass of material, to which due consideration must be given, these authors offer some suggestions of real value. Of these, one is the forceful recommendation of the portable (Benedict) apparatus for making the metabolic tests, as they consider it more reliable, in that it may be carried to the bedside and the studies thus can be made without undue nervous excitement and with the patient free of the effect of physical exertion and, also, free from food influence as the studies can be taken in the morning before breakfast. This is of great importance in obtaining trustworthy results. Another point of considerable interest is the fact that the pulse rate is a fairly constant, though not infallible, guide to the metabolic rate, a pulse rate of over 90 being usually associated with an increased metabolic rate.

With regard to the study of blood sugar in these cases, it is regrettable that a method as simple as Bang's should have been largely discarded, for it is obvious that with our present methods for estimating the sugar tolerance, where two or three c. c. of blood are required, as against two or three drops in the former method, the nervous patient is certain to be influenced by the continued insertion of a needle into a vein at frequent intervals over a two or three hour period. This is a factor not lightly to be reckoned with, for the results are unquestionably rendered less reliable, though the technic is accepted as more accurate.

NEURASTHENIA.

This we formerly regarded as "a maladjustment, a defense reaction against one's environment" as it were, and let it go at that. We have come to realize, however, that many facts concerning these patients repeat themselves in a majority of cases. Heredity may or may not be suggestive. Changes occurring during the developmental period in many instances point to unnatural endocrinal influence and finally, the symptoms which develop following an acute infection or some other equally potent exciting cause, such as nerve strain or worry, and earn for themselves the title of neurasthenic, present, in reality, a typical picture of adrenal insufficiency. Cannot this explain the fatigability, loss of weight and strength, persistent nervousness, apprehension and introspection, the general relaxation of smooth musculature with its accompanying visceroptosis, constipation and often flatfoot, low blood pressure and cold extremities? A lymphocytosis completes this picture of a vegetative nervous system lacking in tone. The part played by the pituitary in this picture is to be conjured with. In other words, given a preformed endocrine instability and add to this a sufficiently powerful exciting cause and we have as a result, a more satisfying as well as a more scientific name for this socalled neurasthenia, which has been the *bête noire* of many generations, but which need no longer remain so, if appropriate treatment is instituted.

EPILEPSY.

Some of these cases fall within the realm of endocrinology, and here again our criteria lie in the hereditary history, the developmental years and the present examination. There are two groups, the first or "distinctly pituitaric type being represented by the adipose, sluggish individual with smooth skin, small genitals, a high sugar tolerance and a small closed in sella turcica. Improvement or even cure may be accomplished by proper administration of pituitary extract. The fit is produced as a symptom, a periodical enlargement of the hypophysis in a sella not roomy enough to accommodate it, causes the explosion" (7).

In the second group we again have heredity and early life factors to consider, and here the condition is regarded as due to retained nitrogenous products, probably split protein and aminoacids. "The retention in the cells of these partial decomposition products acts as an irritant which finally produces the epileptic seizure as a purposeful act, for the convulsion, accompanied by its profuse sweating, increased kidney function and bowel action, tends to relieve this condition."

Kendall explains the retention of aminoacids in the cell by noting that the thyroid gland, through its iodothyroid product, converts the aminoacids into ammonium carbonate, carbon dioxide and water, the ammonium carbonate being probably changed by parathyroid activity into urea.

Thus, if the thyroid parathyroid mechanism is dysfunctioning, these end products of protein metabolism or toxines fail to be adequately eliminated and it may be due to this failure of elimination that the epileptic seizure is provoked, in those patients who have an already unstable glandular activity. Disturbances in the pituitary, ovary or suprarenals, which call forth more than the usual thyroid parathyroid secretion, may thus be underlying causative factors, and the many provocative etiological factors noted in the first part of this paper should be given due consideration in the study of such conditions.

ORGANOTHERAPY.

Many questions referable to organotherapy remain to be answered. I wish to call attention to a few of the more important points.

1. As these extracts are not available from the human being, they are introduced into the body as foreign proteins and must be regarded as such.

2. The chemical action of many of the preparations is undetermined.

3. Some of the reasons for variability of action of organ extracts are as follows: A. The fresh gland deteriorates rapidly at any temperature above freezing and for this reason the best preparations are those which have been completely desiccated within twenty-four hours at low temperature. B. The defatting process is carried out with varying technic and solvents, and by some manufacturers it is not even attempted. C. Owing to the influence of handling and of deterioration, the extracts are probably better administered in capsule rather than in tablet form.

4. As Strauss (8) has noted, there are only three preparations of the specific glands which are standardized; these are the posterior lobe of the pituitary, the thyroid, and the extract of the medulla of the adrenal glands. Even the standardized posterior lobe of the pituitary varies greatly. This comes from the steer, i. e., the adult male and the castration causes many functional and structural changes in the animal, for the most part due to alteration of the pituitary gland secretion.

5. Other gland material varies with different manufacturers, and it is reasonable to assume that some variability of action may naturally occur when different species are used. Thus the thymus comes from the suckling calves or sheep, orchitic substance from bulls or rams, ovarian preparations from the cow or sow, the corpus luteum from the ovary of the pregnant cow, and finally, adrenal gland extracts from male or female, there being no stipulation by the manufacturer as to which sex has been utilized. It would seem that physiological effects might be markedly influenced by variation in sex as well as in species.

The question arises, how may we best overcome these numerous obstacles, and the answer will be somewhat as follows:

1. To stabilize therapeutic results the manufacturers will have to carry out a uniform technic with glands from an accepted series of animals.

2. Standardization will have to be advanced into broader fields.

3. The physician will not only have to abandon the old fashioned methods of administration, but if he is to derive satisfaction in this newer field of therapy, he will have to keep abreast of the times by keeping himself posted on the advances in endocrinology.

4. Careful clinical records of the action of the extracts, it is to be hoped, will accumulate in the coming years and will thus give us a better therapeutic working basis than we have at present.

5. In the use of these substances, the weakest link in the endocrine chain must be recognized, and therapy aimed directly at it, with reinforcements added as indicated.

In conclusion, it might be well to recall that an individual's endocrine tonus may at times determine to quite an extent both his physical and psychic life, that organotherapy offers great promise in the proper balance of this tonus, that the use of the individual extract in moderate doses, as indicated, is far safer than the combined extracts as put out by certain manufacturers, and finally that these socalled polyglandular preparations are untrustworthy and unscientific.

Editorial Articles

THE PROGNOSIS OF CYSTS OF THE THYROID GLAND

Generally speaking, cysts of the thyroid have a benign prognosis when their size is not excessive. There are certain cysts that may give rise to trouble. If the lesion is left alone it may go on increasing indefinitely merely causing some difficulty in movements of the neck, but such is not always the case and complications may arise which greatly aggravate an otherwise good prognosis. The possibility of compression of the respiratory tract, the large vessels and nerves of the neck, constitutes the principal danger of these cysts. The phenomena of compression are frequent and are the consequence of a rapid growth of the tumor due to various influences. Following a violent or spontaneous effort hemorrhage may take place into the cystic cavity with the result that the subject is seized by paroxysms of suffocation that may result in death. An inflammatory process may develop in the cyst and from there invade the entire gland, resulting in paroxysmal attacks of dyspnea which, if in too rapid succession, will end in suffocation.

When the cyst is voluminous it may rupture, its cavity becomes infected and prolonged abundant suppuration menaces the patient's life, while operation in these circumstances is naturally dangerous. Should the abscess rupture into the trachea suffocation is likely, while if this should take place into the pharynx the pus swelling above the epiglottis will flow into the larynx and stifle the patient.

Edema of the glottis is another formidable complication of these cysts. The inflammation may extend to the loose cellular tissue surrounding the trachea resulting in a phlegmon of the neck extending into the mediastinum and axillæ.

Besides these acute complications the tumor may jeopardize the patient's life by compression of the respiratory tract. Usually the cyst is small, hidden behind the sternum during inspiration, but although it may appear to be small it sends off prolongations which compress important organs. The trachea is pushed aside and flattened, sometimes softened; the large veins of the base of the neck are compressed, likewise the origins of the brachial plexus and it is then that there develops venous stasis of the face, neck and upper limb with radiating pain similar to that experienced in angina pectoris. Attacks of dyspnea recur at short intervals, and death results.

All these complications occur rather late in the evolution of the cyst and may never take place even if the cyst becomes very large; nevertheless, an operation should be undertaken at as early a date as possible in order to relieve the patient from any possible complication. Excision of the cystic thyroid when resorted to before any untoward effects of the lesion have been allowed to develop should, with our modern procedures, offer a mortality of *nil*. When any of the complications referred to, especially suppuration of the cyst, have developed, the operative mortality naturally becomes increasingly high.

THE OPTIC NERVE IN EXOPHTHALMIC GOITRE

In Graves's disease the perturbations involving the optic nerve can be divided into two phases occurring in the evolution of the affection. In the first the disturbances are purely functional; in the second the cause persists or becomes accentuated and nutritive disturbances arise with all their consequences, although this outcome is uncommon.

The first effect of exophthalmos is to render the optic nerve tense by strengthening it. The first effect of this traction is borne by the fibrous sheath of the nerve and as it is resistant, the elongation is slow in taking place. Hence the optic nerve does not as yet suffer, while the ciliary nerves which lack protection of this kind, are in this phase more or less tense. But at length the sheath becomes so elongated that the nerve will be directly submitted to the effects of traction. Hence the development of special disturbances whose evolution will follow the oscillations of the exophthalmos.

It is difficult to estimate the degree of elongation which is necessary for the production of functional disturbances of the eye. Marked exophthalmos may not determine any disturbance of the optic nerve while less pronounced cases rapidly cause a loss of visual acuity. When the exophthalmos has given rise to lesions of the nerve they increase or diminish with the cause unless the nerve has undergone structural changes. In certain cases these lesions persist as purely functional disturbances for a long time and visual acuity becomes normal as the exophthalmos diminishes.

In the first place the disturbances are purely functional. Symptoms of irritation of the optic nerve are first to occur—hyperesthesia of the retina, photophobia, and others. Then to this phase of excitation succeeds a phase of depression in which all the symptoms of paresis met with at the onset of progressive optic nerve atrophy will be noted. But the amblyopia rather constantly presents certain peculiarities of importance, in that they allow one to distinguish it from that due to optic nerve atrophy.

The characters offered by the visual field suffice to differentiate unquestionably goitrous amblyopia from the hysterical form and from progressive atrophy of the optic nerve in which the visual field is always changed. If the exophthalmos is accentuated the phenomena of the second phase develop. One of two conditions will be met with. Either the tension of the nerve will result in a true neuritis whose traces will remain for a long time, or else the trophic system of the optic nerve will be involved and a veritable atrophy ensue, which will be readily detected by the ophthalmoscope.

But in exophthalmic goitre these lesions of the optic nerve hardly ever attain an extreme degree. Sight never falls below one tenth. That blindness does not occur is probably due to the fact that the exophthalmos, even in the most pronounced cases, never extends beyond a certain limit and that generally it does not remain long enough in a pronounced degree for structural lesions of the optic nerve to become generalized.

PRESENT DAY ORGANOTHERAPY

At a recent meeting of the British Royal Society of Medicine, Dr. Swale Vincent, of the Middlesex Hospital Medical School, delivered a paper on the Present State of Organotherapy which has been provocative of a great deal of interest. Doctor Vincent opened his discussion by saying: "It has been maintained that, in therapeutics as in other matters, only those methods which are found to be useful and beneficial will ultimately survive. In the ordinary practical affairs of life, this anticipation may be well founded, but in such matters as the employment of various substances to relieve pain, or to restore to normal the deranged machinery of life, it would seem that we cannot even yet trust, either the scientific discrimination of medical men or the common sense of the general public, to eliminate the useless and to hold fast to that which is good." The paper goes on to reveal the grounds for Doctor Vincent's suspicions.

The belief in the efficacy of all the substances involved in the practice of organotherapy is based upon, in Doctor Vincent's opinion, a widely current view in regard to the internal secretions, namely, that all organs and tissues in the body manufacture and pour into the circulation substances whose function it is to regulate the activities of different parts of the nervous system, and so to influence the general metabolic activities of the animal economy; and that any lack or deficiency of these may be supplied by administering preparations containing them. This has led to, among other things, the "untenable hypothesis" of the relation of the secretion of the chromaphil tissues to the circulatory system, and the whole "fabric" of vagotonia and sympathicotonia, so dear to credulous physicians," and has given name to "nonexistent hormones." When physiological experiments failed to demonstrate that all parts of the body furnish internal secretions, and that the organism is likely to suffer a deficiency of any one or of several of these secretions, "a large number of physicians insisted on the value of organic extracts, urging that, though they may contain no physiologically active principles, they are found empirically to do much good in various diseases and disorders." Doctor Vincent believes that in the majority of cases in which this has seemed to be adduced, it was possible at a later period to correlate the observed therapeutic value with a definite pharmacodynamical action.

The next point made is that such substances administered by the mouth have no physiological effects, and when administered subcutaneously or intravenously have only slight temporary influences. In a few cases, growth of young animals has seemed to be affected, but the therapeutic value of these findings is practically negligible. The one and only way to demonstrate the value of a treatment is through a series of careful and accurate experiments, regulated by a system of adequate and rigid controls. Reports of cures of single, separate cases mean practically nothing.

Discussion follows of these findings as applied to thyroid and parathyroid, pituitary, adrenal, testicular and ovarian, and pancreatic medication. The methods of Steinach and Voronoff are commented upon, but, because of their very recent character, no positive opinions are expressed. About the new pancreatic preparations for diabetes, Doctor Vincent says: "It will be wise not to be too sanguine in regard to these . . . but it seems probable that a step in advance has been made, and it is not out of the question that, sooner or later, we may have at our service a preparation made from the pancreas which will benefit diabetic patients in a degree comparable with that of the thyroid extract in myxedema."

Doctor Vincent summarizes his conclusions as follows: "If we seek for cases where it is possible to apply a true substitution therapy—artificially to replace the internal secretions of a gland—we have no clear instance except the solitary one of the thyroid. It may be that we shall before long be able to include the pancreas in this category. There are, however, some few instances where extracts of organs are valuable as drugs, apart altogether from the question of internal secretion. Such are adrenin (given subcutaneously or intravenously) and extracts from the posterior lobe of the pituitary body. Of the rest of the gland and tissue extracts and preparations, it might perhaps be well to say nothing, if it were not that their exploitation on the present day scale constitutes a formidable kind of quackery. There is no subject upon which so much utter nonsense has been talked as upon internal secretions. And organotherapy, for the most part, may be defined as the application of this nonsense to practical medicine."

DEFICIENCY DISEASES

What is the definition, exactly, of a deficiency disease? One does not know exactly what is meant by a deficiency disease. Not long ago the statement was widely prevalent, that a deficiency disease was one in which one or other of the vitamines was absent or impaired and it seemed to be generally understood that vitamine deficiency was the sign manual of a deficiency disease. At the present time no great consideration is shown for the vitamines. It is not that the presence of the vitamine element in a diet is not still recognized as essential to good health, but it has been shown that other constituents are quite as important in a diet as vitamines. The mineral salts and especially the calcium salts, for instance.

It is not so much the lack of a single constituent that impairs health but the error in dieting properly more often lies in want of metabolic equilibrium. In the case of infants and young children both quality and quantity of food are at fault. Infants are often stuffed rather than fed and, of course, when they are stuffed with unsuitable food the results are the worst. But even when feeding with an appropriate diet, a great deal of harm can be done to an infant by cramming it with food. The same remark applies with equal force to the adult. Many men and perhaps more women dig their graves with their teeth. In civilized countries, at least in civilized English speaking countries, more women overeat because, as a rule, they do not take so much exercise as men and consequently their food is not assimilated and digested so thoroughly. In cities, in particular, one of the evils of modern life and perhaps the one most injuriously prejudical to health is eating and drinking more than the human machine requires to maintain it in a highly efficient working order.

It needs but little knowledge to assert that diet is an important factor in preventive medicine. And it can be stated further that if the diet of all was based on scientific principles and particularly the diet of the poorer classes that general health would improve beyond belief. The drawback to our chances of reaching this ideal is that as yet there is no standard by means of which scientific principles of diet can be gauged or approximately gauged. Not long ago a meeting of the Society of English Medical Officers of Health was held in London at which a paper was read by Prof. G. Mellanby, whose work in connection with the causation of rickets is well known in this country. Prof. Mellanby is a confirmed believer in diet as the chief factor in causing rickets, although he may lay too great stress on the influence of the fat soluble vitamine in preventing this condition.

However, little criticism can be rightly directed against his dictum, that persons' tastes are not always a reliable guide as to the best food. For instance, the starchy foods and sugars which children desire are not the foods they most need. Again, in the diet of adults and especially of those of manual workers of the English speaking race, cereals and butchers' meat, which usually take a great place, are supplemented by potatoes, pulses, lard, vegetable margarine, jam, coffee, cocoa and tea while milk, cheese, eggs and green vegetables are neglected. Thus the diet is deficient in vitamines, in the mineral salts, and of calcium salts in particular. In conclusion Prof. Mellanby made the following suggestions.

The consumption of codliver oil should be greatly increased. It is the cheapest source of the vitamine on the market. More milk ought to be consumed. The eating of green vegetables especially raw salads, should be encouraged. Prof. Mellanby would like to see calcium carbonate added to butter and adult diet should be regulated so as to contain more fat soluble vitamine.

It is likely that the value of the vitamines has been somewhat too greatly emphasized. All appear to agree that the diet of the working classes is deficient in fresh food and no doubt the cooking of food does to some extent tend to diminish its nutritive value. Too much cooking does this.

Dr. Harry Campbell, of London, one of the most original thinkers of the day, holds the opinion, and is not chary of expressing it, that when one has one's teeth milk is not needed, and that the consumption of milk and the eating of predigested foods and too much starch and sugar, so common a practice nowadays, are responsible for bad teeth and bad digestion. Dr. Campbell argues that teeth and jaws are constructed in such a manner, and the digestive organs and general plan of the bodily makeup of man is such, that he is intended assuredly to masticate vigorously hard food and not the soft prepared food with which he is wont to overload his stomach, a habit which is prone to induce that frequent condition of modern civilization, intestinal stasis.

The disorders of digestion deserve more close and patient study than any other disorder to which man is prone, for the reason that these are the origin of most of human diseases and conditions of ill health. So far as treatment is concerned, as is pointed out in *Medical Press and Circular*, for February 7, 1923, the fact has not yet been grasped that nineteen twentieths of the treatment of digestive disorders is prophylactic, and consists in due attention to diet. In many respects views as to diet require further study and a considerable amount of revision.

DUPING THE PUBLIC

The series of articles by "Dr." Paul de Kruif running in *Hearst's International Magazine*, and attacking in a most insulting manner the medical profession and its practices, is written in a spirit of such spiteful animosity, such apparently willful ignoring of actual facts, that it is clearly evident that the writer's attitude of mind must arise either from some childish personal bias or grudge, or from a desire for cheap notoriety through rushing into print about things, about which he is totally ignorant, to a reading public notably deficient in educated intelligence, and gullible enough to swallow any kind of bunk. From the point of view of the physician, such articles are only to be ignored, or, at most, to be passed over with a laugh, but there is another and more serious aspect to the problem—that of the popular mind, which will accept the untruths and inconsistencies, and undoubtedly be influenced by them, unless they are publicly contradicted and disproved. Picture the farreaching, detrimental effects upon the unthinking, gullible readers of sensational literature of the following: "If the profession does not wash its own dirty linen, the disagreeable duty will have to be done by others. That is the principal purpose of this series. If doctors insist on being fooled, some power will have to arise that will make it harder for them to be fooled. If they continue to follow the siren voices of drug mongers, and use nostrums that may actually endanger lives, some method must be devised to keep such tools out of their hands. The many doctors who treat their patients indiscriminately with these products do so out of ignorance and commercialism. After all, the only value they know to exist for the injection is the five dollars that they will get on the first of the following month."

It is easy to see that it is not the intelligent, well informed people who will be influenced by such statements, but the large class of ignorant readers who will take the articles seriously, accepting these verbigerations as truths, becoming more and more bitter, from lack of understanding or some unfortunate personal experience, against medical treatment, and so cut themselves off from the benefits to be derived from it. The large class of decent and intelligent men and women, however, who are conversant with the standards, aims, and achievements of the recognized medical profession, will never be influenced by literature so evidently published for purposes of propaganda, so full of extravagant and exaggerated statements, and so lacking in a foundation of facts. They will realize that medicine must have its limitations by the very nature of the material with which it deals, but they will also know, through their own intelligence and from personal experiences, the qualifications and ability of the capable physician to minister to the human organism and its afflictions.

COURSE IN NEUROPSYCHIATRY TO BE GIVEN BY VETERANS' BUREAU

A special course in neuropsychiatry is offered by the United States Veterans' Bureau to a certain number of qualified physicians. The bureau's policy is to provide expert medical attention for disabled veterans in order that they may be restored as quickly as possible to health and to a proper place in community life. In carrying out this purpose it was found that the available specialists in nervous and mental diseases were not numerous enough to supply the demand. The course will continue for about four months, and will consist of about 176 lectures and 440 hours of clinical and laboratory work. Special attention will be given to diagnosis, general care, and methods of treatment. The general problems of hospital administration, medicolegal questions, rehabilitation and reeducation, and psychological examinations will also be covered. The main part of the course will be given at St. Elizabeth's Hospital at Washington. Other public hospitals in Washington will provide abundant clinics in functional disease, borderline cases, and the milder types of mental and nervous disturbances. On satisfactory completion of the course, the student will be recommended for the grade of passed assistant surgeon in the Reserve Corps of the U. S. Public Health Service, or will become eligible for employment as Class B physician under the U. S. Civil Service Commission and assignment to duty with the Veterans' Bureau. Application for taking the course must be made to the director of the U. S. Veterans' Bureau. Washington, D. C.

CANCER MORTALITY IN 1921

The Department of Commerce has announced that the returns compiled by the Census Bureau show that more than seventy-six thousand deaths from cancer occurred in the death registration area of the United States during 1921. Assuming that the remainder of the country had as many deaths from this cause in proportion to the population, the total number of deaths from cancer in the entire United States for 1921 was ninety-three thousand. For 1920, the number is estimated as eighty-nine thousand or four thousand less than for 1921, or, in 1921, eighty-six to the one hundred thousand population against 83.4 for 1920. The Bureau has used "adjusted" rates in order to make allowance for differences in the age and sex distribution of the population, because, as a rule, only persons in middle and old age have cancer, so that a State with many old people may be expected to have more deaths from cancer than a State with comparatively few old persons. The highest adjusted cancer rate for 1921 is 99.6 to the one hundred thousand population for Massachusetts, and the lowest is 47.6 for South Carolina. In the case of a few of the States, separate adjusted rates for the white and colored population have been calculated. In this group of States, the highest adjusted cancer rate for the white population is 95.9 to the one hundred thousand for New York, and the highest rate for the colored population is 90.6, also for New York. The lowest adjusted cancer rate for the white population is 51.5 for Tennessee, and the lowest for the colored population is 36.4 for Florida. The adjusted rates show that the Northern States have comparatively high, and the Southern States comparatively low, cancer mortality, and that there is little difference between the adjusted rates of the white and colored races of the same States.

CHILD WELFARE IN ROUMANIA

The American Red Cross, in 1919, first established child welfare stations in Roumania in response to an appeal from the government for their assistance in combating the alarmingly high rate of infant mortality. It was decided, after a conference of the Red Cross and the most important Roumanian welfare organizations, that the most practical form which the projected relief could take would be the establishment of an efficient nursing service on public health lines, particularly in its relation to child welfare. Activities began in 1920, when several British trained nurses were sent to Roumania to take over and expand, for a period of six months, the child welfare work begun by the American Red Cross in the clinics of several cities. By the end of the year, the clinics were progressing favorably, volunteers had been secured and were being trained, and a course of instruction for Roumanian nurses had been arranged and given in the form of weekly lectures. In 1921, it was decided that, on the completion of the six months' work in the clinics, a centre for training young women in the aftercare of maternity cases and in the care of children should be established at Bucharest. The Xenocrat Hospital in this city was taken over, equipped and maintained as a school for training twenty-five pupils from all parts of the country in practical methods of child welfare. Later in the same year, a training school for midwives in child welfare was also opened at the Xenocrat Hospital. The work progressed so rapidly and so favorably that during 1922 twenty-five dispensaries for babies were opened in the provinces, a travelling dispensary was established, and two mobile units for giving lectures and demonstrations.

NEW MENTAL HYGIENE BULLETIN

A new publication treating of current events in the field of mental hygiene is being issued, beginning with the January number, by the National Committee for Mental Hygiene. The title is *Mental Hygiene Bulletin*, and it will be published every month except July. The announcement states that the section in the official organ of the committee, *Mental Hygiene,* devoted to items of news and entitled Notes and Comments, has of late needed so much space that the editors have found it impossible to make room, even for the major items. It was evident, therefore, that there was need of a more frequent publication to disseminate information to those interested in current events. For this purpose the *Mental Hygiene Bulletin* will be issued and will record events whose importance lies not so much in their permanence as in their timeliness. Dr. Frankwood E. Williams, director of the National Committee for Mental Hygiene and editor of *Mental Hygiene,* is editor of the *Bulletin.*

ENDOCRINE LITERATURE

In the manner of the NEW YORK MEDICAL JOURNAL AND MEDICAL RECORD the *Prescriber* (Edinburgh, October, 1922) has assembled an extremely interesting group of papers on the topics of thyroid and parathyroids in a special endocrine number. Stanley Jones writes on the thyroid in acute infections, H. Ewan Waller on Graves's disease, Ivo Geikie Cobb on thyroid therapy, Philip A. Harry on the thyroid in eye disease, Thomas Stephenson on thyroxin, and H. W. C. Vines has a paper on the parathyroids. There is a goodly review of the literature. All in all it is a well assembled number and shows an effort on the part of the editor to serve the readers of the *Prescriber* with material of a stimulating and valuable character.

◆

News Items.

Antivivisection Bills Killed.—The Assembly Codes Committee voted unanimously to kill the Cotillo-Leininger Antivivisection bills. One was designed to prevent "experimentation" on children, and the other would have prevented surgeons from making experiments on living dogs. Assemblyman Duke, chairman of the committee, declared the real purpose of the child bill was "to advance Christian Science" by preventing medical treatment for children unless their parents consented. The penal law now forces parents to provide medical treatment for their children.

Encephalitis Lethargica.—According to reports made to the Division of Communicable Diseases of the New York State Department of Health, 308 cases of encephalitis lethargica occurred in New York State during February of this year, which is more than in any other month during the last two years. With the exception of February, 1921, the month of February this year also shows the highest record for cases of this disease in upstate New York.

American Medical Association Tour.—The train for the special twenty-five day tour from New York City to the meeting of the American Medical Association in San Francisco, organized under the auspices of the Medical Society of the State of New York, is already filled. Another train will be arranged for if 125 more subscribers can be secured. In order to do this, however, it will be necessary for applications to be in not later than April 15th. Applications should be sent direct to Mr. J. S. McAndrew, tour manager, Lifsey Tours, Inc., 1472 Broadway, New York.

$1,500,000 School for Mt. Sinai Nurses.—Plans have been made for a $1,500,000 training school for nurses at Mt. Sinai Hospital, it was announced by Leo Arnstein, acting president, at the annual meeting in Blumenthal's Auditorium, 1 East Ninety-ninth Street. The new structure will be the eighteenth building maintained and supervised by the institution. Half the cost has been promised by the trustees. The school will accommodate 400 nurses, as against only 220 who are housed in the present building on Madison Avenue. It will be built on a plot 100 by 125 feet. Mrs. Otto H. Kahn gave the hospital an adjoining lot on Ninety-ninth Street near Fifth Avenue to form part of the plot.

Jewish Hospital Will Be Enlarged.—More than a thousand persons participated in the laying of the cornerstone of the new $500,000 wing of the Jewish Hospital in Brooklyn, known as the Abraham Abraham Memorial. The construction of the new wing was made possible by the initial gifts of the widow of Abraham Abraham, a merchant and philanthropist, who was the first president of the institution. During the ceremonies officials of the Jewish Hospital announced the completion of plans for the construction of another wing to the building and the donation of $75,000 needed for the work. It was announced that the hospital had taken title to sixteen lots adjoining the site of the new memorial.

Pasteur Performance Given for Academy of Medicine Fund.—Members of the Academy of Medicine and their friends attended a benefit performance of *Pasteur*, given by Henry Miller and his company at the Empire Theatre. Mr. Miller gave the performance to aid the fund that has been started by the Academy to raise $250,000 to carry out an arrangement with the Rockefeller Foundation and the Carnegie Corporation for the building and equipment of a new building at Park Avenue and Sixtieth Street.

Mr. Miller and Dr. Edward L. Keyes, Jr., made short addresses after the second act. Dr. Keyes read a message of regret from Ambassador Jusserand, who said that he had not sufficiently recovered from a recent illness to attend. Some $50,000 has already been pledged, Dr. Keyes told the audience.

Western Electrotherapeutic Association Meeting.—The Western Electrotherapeutic Association's fifth annual meeting will be held in Kansas City, Mo., on Thursday and Friday, April 19 and 20, 1923.

Bronchoscopic Society.—The annual meeting of the Bronchoscopic Society will take place in Atlantic City at the Ambassador Hotel, Wednesday, May 9th at 9 a. m., on the day preceding the meeting of the American Laryngological, Rhinological and Otological Society.

Lenox Hill Hospital Meeting.—The Clinical Society of the Lenox Hill Hospital held a special meeting on Friday, March 23, 1923, at 8.30 p. m. sharp. By invitation Professor Dr. Oskar Frankl, of the University of Vienna, addressed the meeting in English. His subject was The Relationship Between Gastrointestinal Carcinoma and the Female Sexual Organs.

Eastern Medical Society.—The Eastern Medical Society announces a dinner and dance for their Loan and Relief Fund which will take place on Sunday evening, May 6, 1923, at the Hotel Astor (Grand Ball Room). This affair promises to be the most brilliant medical social gathering of the year. The charge will be $5 a person. No reservations accepted unless accompanied by check. Remittance may be made to Abraham Strachstein, secretary-treasurer, 17 East Thirty-eighth Street.

New York Electrotherapeutic Society Election.—At the recent annual meeting of the New York Electrotherapeutic Society held on February 27, 1923, at the New York Academy of Medicine, the following officers were reelected: President, Dr. Victor C. Pedersen; vice-presidents, Dr. Harry E. Stewart and Dr. Sinclair Tousey; treasurer, Dr. J. Willard Travell; secretary, Dr. Richard Kovacs; members of the executive committee, Dr. Frederick DeKraft, Dr. A. Bern Hirsh, and Dr. William Benham Snow.

American Proctologic Society.—The preliminary program of the twenty-fourth annual meeting of the American Proctologic Society at Los Angeles, Cal., on June 22 and 23, 1922, has been published. The profession is cordially invited to attend the public sessions, which will be held at the Hotel Alexandria and the Los Angeles County Hospital. In addition to the regular papers, at convenient times during the scientific and clinical sessions, there will be demonstration of instruments and operative technic and discussion of several important proctological subjects as requested by certain Fellows.

Women's Medical Society Convention.—The Women's Medical Society of New York State will hold its eighteenth annual convention in the McAlpin Hotel, New York City, on May 21st.

Many of the doctors will remain for the Scientific Session of the State Medical Society. The scientific session will be composed of a symposium on Eye Diseases in Relation to General Medicine, Feeble Mindedness in Relation to Prostitution, Early Symptoms of Carcinoma of the Cervix, Observations Concerning Gastric Disturbances, and others to be announced later. Arrangements for the convention are in the hands of Dr. Ethel Doty Brown. Reservations for the dinner must be made before Saturday, May 19th. Check for $4 should be sent to Dr. Ethel D. Brown, 26 Gramercy Park, New York.

LONDON LETTER.

(*From our own correspondent*)

LONDON, *March* 6, 1923

DRUG ADDICTION.

Drug addiction in this country is very considerably on the increase. The daily journals are full of its effects and of accounts of prosecutions to do away with the illegitimate sale of cocaine, opium derivatives, and so on. To obtain certain habit forming drugs subterfuges of every kind are resorted to and the police are on the lookout constantly to defeat the ingenious tricks by which the ends of justice in this respect are frequently evaded. At the present time cocaine appears to be the drug of choice here. There is a good deal of talk concerning the horrors of barbarism and the civilized man, presumably Christian, at least, more or less so, is often given to deploring the vices of the poor benighted savage. When, however, all the circumstances are taken into consideration, the bad habits of primitive people are no worse, if so bad, as those of civilized communities. The horrors of barbarism in many respects shrink into insignificance in comparison with the horrors of civilization. In fact, while some of the increase of the drug habit may be attributed to the aftereffects of the war it is more likely to be due to socalled advanced civilization. Progress of civilization is accompanied by progress in vice or vicious habits and *pari passu* with great discoveries, the advance of science, the arts, and above all the art or knack of making money, came luxury and artificial bad habits of every description. The reading of history shows plainly that this statement is true. All nations of the past which have risen to great heights of civilization have become rotten through luxury and have excelled as greatly in moral and social evils as in culture. Ultracivilization has produced ultravices. Witness Egypt, Babylon, Greece and Rome, and especially Greece.

At the present time in this country, and in London, in particular, a loud outcry is being raised against the indiscriminate use of powerful narcotics. Mental balance in these exciting stirring times is not what it was in quieter periods. The manner of life generally predisposes those of imperfect mental balance, and there are many such, to seek new forms of excitement, or rather perhaps to gain temporary forgetfulness, and the attempt is made to achieve this object by means of drugs. Strong drink nowadays is regarded by these ultracivilized to be too gross a mode for finding brief oblivion and the weak and the viciously inclined fly to the murderous narcotics, such as cocaine, morphine and opium.

BIRTH CONTROL.

This is another question which is greatly exercising the minds of the public at large and of the members of the medical profession in particular. It is a matter which closely concerns all and the medical man from more than one point of view. Perhaps it is essentially an economic question. This country is greatly overpopulated. More than two thirds of its population live in cities or towns. It cannot, or at any rate, does not nearly feed its inhabitants. The greater part of its food is imported and agriculture is so handicapped that unless drastic steps are taken to assist the home farmer, conditions will become such that more food will have to be imported. It is being asked on all sides, What is the remedy for this overpopulation? Emigration is that which most forcibly suggests itself. But the arguments against emigration on a wide scale are strong and very much to the point. Neither America nor our own Dominions will accept any but the best stock and this is the stock we can least spare. It would be disastrous if this land were denuded of its hardiest and most energetic members. Therefore emigration will not solve the problem but will rather accentuate the difficulties. The most sinister feature of the situation is that the worst class of town dwellers are increasing out of all proportion. Those who have the largest families are the least able to rear and educate them and instead of being a benefit to the country they are too frequently a source of danger. On the other hand, those who are best equipped mentally and physically to breed and bring up children who will be a true asset to the nation have the smallest families. Many of them, perhaps most of them, have the smallest number of children because they voluntarily restrict the number. It is argued that it is folly to bring children into the world who will have little chance of prospering and that it is wiser to have one or two who may have the opportunity of living decently and comfortably, than several who in an already greatly overpopulated country, will be denied this opportunity.

To be really effective the poor should know how to bring about birth control. Many well known British physicians and surgeons are in favor of knowledge of this nature being disseminated among all classes of society and especially among the poorer classes, where big families are often not only a burden, as emphasized previously, to those who have them, but a danger to the community at large. It is significant that the subject is now openly discussed and that prominent men of every profession and of the medical profession in particular avow themselves supporters of the movement. In any event, it certainly is to the benefit of all that the question should be considered and discussed from every possible angle. Population is increasing in Europe to such an extent, and the opportunities for gaining a livelihood are proportionately decreasing, owing largely to the effects of the war, that unless feasible and reasonable means are found to relieve the situation, disaster must ensue.

REVIEW OF THE REGISTRAR GENERAL OF ENGLAND AND WALES FOR 1922.

The Review of the Registrar General for England and Wales for 1922 has just been issued. According to this review and the quarterly return for the last quarter of 1922 which was published with it, the natural increase of population in that year was 293,358. Infant mortality, estimated per thousand births, was seventy-seven, the lowest figure ever recorded, the next lowest having been eighty in 1920. There was no infantile diarrhea due no doubt to the wet summer, which was in this respect a blessing in disguise. Generally speaking the year was healthy and the death rate lower than prewar rates, which seems to dissipate the idea that the postwar population would be relatively more unfit than the prewar population. The birth rate is falling. The decrease, however, may be due mainly to the hard times through which we are passing. In London chest diseases, such as bronchitis and pneumonia, were the most prevalent and fatal. Heart diseases came next on the list of fatal diseases and bronchitis and pneumonia were increased considerably by influenza. Cancer, as in the past two or three years, held third place.

THE NEW DIRECTOR GENERAL OF THE BRITISH ARMY MEDICAL SERVICE.

Almost for the first time a great medical scientific investigator has been appointed to the position of Director General of the British Army Medical Service. Sir William Leishman, the new director, is easily one of the most distinguished investigators who has served at any time in the medical service of the British Army. He has held the posts of assistant professor of pathology at the Royal Army Medical School, and of professor of pathology at the Royal Army Medical College. He has been president of the Society of Tropical Medicine and Hygiene and member of the West African Fever Commission and of the Medical and Sanitary Committee of Tropical Africa. But his chief claims to fame rest on his discovery of the causal organism of kala-azar and on his investigations into the causes of tropical diseases generally. The British Army authorities have scarcely recognized their many eminent research workers as they deserved to be recognized. Sir Ronald Ross drew attention to this in a speech a short time ago. Sir Almroth Wright was in the army, but retired many years ago to pursue his researches under more favorable conditions. Several other well known medical scientific investigators have left the army for similar reasons. In this country medical science has been treated rather badly.

Medical men who have done most important work in research have been compelled to discontinue for lack of funds and really to waste their abilities in the practice of their profession in order to gain a bare livelihood. These men if they had not been hampered by want of money might have made discoveries to the lasting good of the race. In Great Britain the government has been penurious with regard to encouraging medical research because a public ignorant of its value has not demanded that it be encouraged. The public here have not been educated in this direction as they have in the United States. The rich men of America understand the benefits that discoveries in medicine leading to the prevention, relief, and abolition of disease and to the improvement of the general health, may and will confer on the community, and they devote large sums to the advancement of medical research. The wealthy here are beginning to be impressed with the potentialities of medical research and are unloosing their pursestrings more freely than formerly to aid in its development, but they are still far behind American millionaires. The general public appear to care nothing for medical research and consequently the government is slow to move. A speaker the other day, I think it was Lord Willoughby de Broke, referring to the great foresight of Disraeli, commented on the fact that that great statesman enunciated more than once that obviously true statement that the good health of its inhabitants was the greatest asset of a nation by far. However, there are few British politicians of the day who have the farseeing statesmanlike imagination of Disraeli and therefore as Sir Ronald Ross deplored allow medical research to languish because they have not the imagination and the backbone to look beyond the gaining of votes and to so endow medical investigators that they can work untrammelled by the pinch of poverty and thus give of their best. Undoubtedly this is a shortsighted policy, "penny wise and pound foolish."

POSTGRADUATE MEDICAL TEACHING IN LONDON.

On February 16th last a meeting of the General Council of the Fellowship of Medicine and Postgraduate Medical Association was held at the Royal Society of Medicine in London. A discussion took place on the recommendations of the General Purposes Subcommittee as regards a postgraduate school for London, which took the following form: 1. That the postgraduate school in London should be a school of the university. 2. That the postgraduate school should comprise, a, a central administration office; b, a large general hospital, and, c, approved special hospitals. 3. That a dean be appointed to act as the principal officer of the central organization and to direct medical study. 4. That the general hospital should contain at least two hundred to three hundred beds and properly equipped laboratories and lecture and demonstration rooms. The general hospital should be in a central situation and possess facilities for social meetings. 5. That every opportunity should be afforded for lectures on demonstrations by persons other than members of the staff of the postgraduate school and that resident and other appointments should be open to postgraduates. 6. That the general hospital of the school should be one of the existing undergraduate teaching hospitals in a central position and should not take undergraduates.

Mr. J. H. Waring, speaking on behalf of the University of London, said that the university felt strongly the need for a postgraduate school and urged the fellowship to get into touch with the university. Although the movement for the establishment for a postgraduate medical school in London while allowedly greatly needed, does not seem to make the desired progress, in fact, appears to strangely hang fire. Recently there has been more energy displayed in bringing matters to a head. Undoubtedly the organization of the scheme is not so satisfactory as it might be, but signs are apparent that some of the defects of organization will soon be remedied. Much valuable time has been lost in getting the scheme into working order and the only remark now to be made is better late than enver.

NEW EDITION OF LANGDON BROWN'S BOOK.

The second edition of Dr. W. Langdon Brown's book on the *Sympathetic Nervous System in Disease* has been issued recently by Henry Frowde and Hodder and Stoughton. The work is based upon the Croonian Lectures delivered before the Royal College of Physicians of London in 1918. This book may be termed highly instructive and interesting. The object of the author has been to illustrate the relations of the autonomic system to a few large groups of disease, as, for example, affections of the endocrine glands, of the digestive and circulatory systems and glycosuria. The main point which Dr. Langdon Brown emphasizes is the intimate interaction of the endocrine glands with the sympathetic nervous system, as well as with the reproductive organs. And this fact is enlarged upon as of first importance, if the emotional response of the sympathetic nervous system and the influence of emotion on structure are to be estimated at their true value. Sufficient attention has not been paid to the effect of emotion on the nervous system and structure in all its bearings. As a matter of fact, we are only now beginning to understand the real functions of the endocrine glands and the part they play in the causation of disease and conditions of ill health. Their close interaction then with the sympathetic nervous system and the reproductive organs is obviously a point of the greatest medical concern and must bulk largely in treatment. Perhaps a thorough knowledge of the endocrine glands is the key of all successful treatment. At any rate the more we learn of them the more we are impressed with their vital importance and the more we earnestly desire to unravel their many yet unsolved mysteries. Dr. Langdon Brown has briefly but clearly dealt with our present knowledge of the sympathetic nervous system and its relations to certain diseases. It may be said that he is a pioneer in this direction and that his little book is a valuable contribution to the study of the unconscious, a study which is making progress mainly by means of the author and others like him who pursue their investigations from a strictly scientific standpoint.

THE HOUSING QUESTION AND THE MINISTER OF HEALTH.

Good houses are essential to good health, and, moreover, a sufficiency of good houses is essential to good health. Even before the war there was an inadequate supply of houses in this country and, of course, the war made matters much worse, as during the war no building and little repairing was done and for some time after the war the cost of building was almost prohibitive. The consequence is that at the present time there is a deplorable scarcity of houses, a situation which militates against good health and good morals. The policy of the government on the housing question is very unpopular, as it places a large part of the cost upon the local authorities already overburdened by rates. Workingmen cannot afford to rent these new decently built houses and therefore it is proposed that the government and the local authorities shall make up the deficit. There are other points involved one of which is that the government propose to remove the control of house rent. However, it is outside the province of a letter to a medical journal to descant on politics and it is only the intimate connection between housing and health that makes the subject at all pertinent. The Minister of Health, Sir A. Griffith Boscawen, at the time of writing, has not a seat in the House of Commons. He was defeated at the general election and has been waiting for a safe seat. It was thought that such had been found but it seems now that he will again be unsuccessful. The result of the poll will be known today. If he does not get in he will retire and a new Minister of Health will be appointed. The housing question comes within the aegis of the Minister of Health and was the cause of the downfall of its first minister, Dr. Christopher Addison.

YOUTH AND DRINK.

Lady Astor has introduced a bill into the House of Commons to prevent the sale of intoxicating liquor in public houses to young people under eighteen years of age. This bill will receive strong support.

SCIENCE MASTERS' CONFERENCE AT CAMBRIDGE.

A conference of the Science Masters' Association has just been held in Cambridge. Among the lectures of interest given was one by Mr. A. Wood on the acoustics of public buildings. This lecture was given in the Cavendish Laboratory, famous throughout the civilized world for its influence in research. Mr. Wood said that the first really scientific study of the problem of acoustics came from Professor Sabine, of Cambridge, Mass. He had decided quite definitely that the trouble with the bad auditorium was reverberation. This reverberation was the persistence of sounds sometimes for as long as six seconds after their delivery. The problem resolved itself into absorbing the sound. Professor Sabine had discovered that the introduction of cushions would reduce the reverberation. The theory had been established that the acoustics of a building depended on the material of which it was constructed, and the reverberation of an acoustically bad building could be greatly improved by the introduction of felt or similar material. There was another trouble which Sabine had solved, and this was by means of the echo photograph. The sound waves within a building and the path of any echo could be traced, and either its cause removed or the echo trapped. In conclusion, Mr. Wood remarked that it only remained to persuade architects that they should let science assist them in acoustics.

VIENNA LETTER

(*From our own correspondent*)

Vienna, *February* 22, 1923

SPIRITUAL HEALING OF DISEASES OF THE LUNG.

In a medical meeting held in Koesen, Germany, there was an interesting dispute on the spiritual healing of some diseases of the lung. This new fad has many advocates, who are going to found the World Federation of Spiritual Healers. Their motto is: "There is no bodily evil." "The freshness of the soul or its downtroddenness, the balancedness of our soul, or its impairment is the source of health and disease, respectively. We all carry in our body the germ of one or another disease," said one of the speakers, and quoted the well known saying of Prof. Robert Koch, the discoverer of the bacillus of tuberculosis: "All of us are a bit lung patients." This and other diseases are provoked later on by the thousand fights of life, according to the presence of the germs which are slumbering. A pathologist of the Vienna University Clinic, said the chairman of the meeting, who has made several thousands of dissections, has made the discovery, that very many old men die from marasmus, in whose lungs extensive tuberculotic foci are found by dissection. Some of these foci were already healed, but many are still virulent, with which they ought to have died long ago. Many eminent doctors have dealt with this question, thoroughly, but failed to solve this puzzle. Now the key of this secret has been found at last! We are able to remain healthy if we preserve the freshness of our soul, if we do not force our strength in the service of such aims, under which our spiritual energy is breaking.

Our body, the advocates of the new theory say, is only the valet of our soul; the body follows the directions which the soul issues. For, is there any body, who has not seen or felt what powerful energies can be provoked by good news, and every one of us has seen, pale, flaccid faces, which carry the scriptures of broken, careworn souls?

According to the ideas evolved at the Koesen meeting we ourselves are the governors of our welfare. He who can steer the sails of his soul with the winds of good humor, would not easily get in spiritual whirls, and is capable of removing all invasions with fresh, steely muscles from himself, and keep away the greatest enemy of our life: death.

THE SON OF THE SULTAN A DERMATOLOGIST.

It is reported from Constantinople that Zia-Eddin Hendi, Turkish Prince, son of the late Sultan, has passed the final examination at the medical faculty of the local university, and after being graduated, has commenced medical practice, as a specialist in dermatological diseases. Zia-Eddin is the eldest son of the late Mohamed Resad, and is fifty years of age. He is the first Turkish Prince who selected as a career a civilian occupation. During his university studies he was known as the most diligent and laborious student, who passed all his examinations with eminent results, and was noted from the fact that during the ten seasons he did not miss one single lecture.

THE COCAINE EPIDEMIC IN VIENNA.

As all scourges which start from the West reach also the East, so cocainism, with all its unfortunate evils, arrived in Vienna. The police authorities had already been informed several months ago that in Vienna cocaine intoxications are of daily occurrence; they could not, however, do anything until a concrete case was reported to them. This happened a few days ago, when a high State official notified the public sanitation office that he had to take his son to the Wagner-Jauregg Clinic by reason of severe toxic symptoms, arising from the consumption of cocaine, in several cabarets near the opera house. The sanitation office has handed the affair to the police in order to investigate the places where revelling with cocaine is done. They found out that almost all night localities are provided with secret rooms, where the consumption of cocaine is connected with sexual perversities. The cocaine is mostly smuggled, but great quantities are bought in apothecaries by producing out of date medical prescriptions, and fresh prescriptions are ordered in twenty to thirty apothecaries. But the worst is that they have found medical men, too, who if well paid give prescriptions for cocaine without question. This is not at all to be wondered at, if we reflect that in Vienna there are hundreds of doctors who do not earn sufficient to make it possible for them to eat meat once in three days. The public sanitation office has sent a memorandum to the Medical Chamber asking this body to instruct its members not to give prescriptions for cocaine without due indication, and shall not fail to note on every prescription that cocaine can be served only once for it!

INCREASED MORTALITY RATE IN GERMANY.

On Monday, February 7th, Professor Bumm, chairman of the Public Sanitation Office, read his report in the session of the Imperial Parliament in Berlin. According to this report the sanitary conditions, which in prewar times have been the best in the world, and enview by the most cultured countries of the globe, are steadily deteriorating owing to the scarcity of food, and lack of fuel, and lack of money for public cleanliness. This is most felt in the larger cities and in industrial centres. Meat has become a luxury for the greatest part of the population, to be indulged in only once in a week or so. The dwellings do not meet even the most modest sanitary requirements. By reason of this the mortality rate is ever on the increase. It grew from 12.6 per cent. in 1921 to 13.4 per cent. in 1922. The increase is greatly due to the spread of suicides, which took frightening proportions lately. Many infants' homes had to be closed by reason of the scarcity of milk. The mortality of children exceeds all previous records; for the majority of death among children tuberculosis is responsible.

A CASE OF INDEMNITY AGAINST PROFESSOR WAGNER JAUREGG IN VIENNA.

Anna Hoffmann, the divorced wife of a police inspector, has sued Professor Julius Wagner-Jauregg, the world known psychiatrist, for damages, arguing that she was improperly treated for paralysis in his clinic, receiving injections that have caused manifestations of lameness. She was taken from Jauregg's clinic to Steinhof into the state asylum, where she was kept imprisoned for eighteen months, according to her statement, contrary to right and law. Professor Jauregg declared that the suspicion of paralysis was quite justified in the case of the plaintiff, and in such cases it is but natural that lumbar puncture is administered, which is not connected with any danger, considering the great practice and skill of his staff in employing it. All the witnesses who have been heard verified that the plaintiff had external symptoms of paralysis and therefore the lumbar puncture was necessary. He denied that she had been illegally detained in the lunatic asylum at Steinhof. The plaintiff's complaint that she had manifestations of lameness was not true; neither he, nor his staff, not even the lay relatives or friends of the patient had ever noticed symptoms of lameness. On the contrary, he (Professor Jauregg) was very proud of the case, as being a healed paralysis, thanks to a new drug, lately introduced, and at present largely experimented with in his clinic. The jury has, of course, refused the claims for damages, and the President of the Assizes remarked, that since the Minister of Justice had allowed that certified poor people were permitted to sue one without paying the state stamps, such cases were brought before him in an exceedingly great number. This was an unjustified molestation of notable men, whose time was too valuable to spend whole forenoons before the court. He felt induced, he concluded, to send a memorandum to the Minister of Justice, to appoint a committee consisting of legal men, and delegates from the Chamber of Physicians, to conduct a preliminary investigation of all such cases before undertaking the charges against notable medical men.

Book Reviews

ENDOCRINOLOGY.

The Organs of Internal Secretion. By Ivo Geikie Cobb, M.D., M.R.C.S. New York: William Wood & Co., 1919.

In this compact guidebook Cobb gives a concise general résumé of endocrinology. Many points of value are mentioned. Of especial interest are his notes on the use of thyroid feeding. The text is clearly written and the book should prove more useful than some of the more flamboyant outbursts which have appeared recently on the subject of endocrinology. Cobb is known to the readers of this Journal through his original contributions to the special endocrine numbers.

TESTICULAR GRAFTS.

La Greffes Testiculaires. Par le Docteur Serge Voronoff. Avec 19 planches. Paris: Octave Doin, 1923.

It may be his technic or his careful selection of cases and material that causes Voronoff to succeed where others have failed. At any rate he has gone on courageously and followed a field of work which seemed hopeless at first. The technic is carefully explained in the present book and from this point of view it should be studied with care.

INTERNAL SECRETIONS

Innere Sekretion. Von Prof. Dr. Artur Beidl. Berlin: Urban & Schwarzenberg, 1922. Pp. 338. Pp. 480.

This is one of the briefest and most comprehensive works covering the field of endocrinology. It is two years since the publication of the first edition, this being the second, and at present Russian and Spanish translations are being printed. Biedl's work is well known and frequently quoted in this country. This is a helpful and very useful monograph.

PHYSIOLOGICAL CHEMISTRY

Practical Physiological Chemistry. By Philip B. Hawk, M.S., Ph.D. Eighth Edition, Revised. With two full page plates of Absorption Spectra in colors. Four additional full page color plates and 197 figures of which twelve are in colors. Philadelphia: P. Blakiston's Son & Co., 1923.

Less than eighteen months after the seventh edition left the press, this latest edition has become necessary, showing the measure of continued approval which this most excellent work has earned in the minds of teachers of physiological chemistry in English speaking countries.

The entire volume has been revised and much new matter added to include the most recent researches. Most of the new matter has been introduced under the sections on blood analysis, acidosis, kidney function, vitamines, and quantitative urine analysis. Benedict's quantitative test for sugar in urine and Folin's quantitative test for albumin, devised after the volume had gone to press, are made available in the form of an addendum in the end of the book. The author believes that these two tests mark a distinct advance in the procedures available for the clinical examination of the urine.

In its present enlarged and revised form there is no doubt but that this work will be accorded the same measure of popularity which has been given its predecessors.

IMMUNITY

How We Resist Disease; An Introduction to Immunity. By Jean Broadhurst, Ph.D., Philadelphia and London: J. B. Lippincott Company, 1923. Pp. 248.

The design of the book is to provide for nurses and general college students a brief introduction to the technical and apparently limitless field of immunity. The main principles of immunity are given in language as simple as possible, with outlines of the most important preventive and curative practices. Much attention has been given to the numerous plates and illustrations with their accompanying explanations. These constitute one of the valuable features of the book. As few technical terms as possible have been used, but when this was unavoidable; they are fully explained in a glossary appended to the volume. The author has not attempted to include in a textbook for beginners any controversial material except that necessary to a general knowledge of the subjects discussed. These subjects are: Bacteria and their effects upon the human body; active immunity; passive immunity; toxins and antitoxins; agglutinins and precipitins; opsonins; white corpuscles; lysins; vaccines; anaphylaxis.

CELLULAR DESTRUCTION.

Les Phénomènes de destruction cellulaire: autolyse, hémolyse, bactériolyse, organolyse; l'importance de leur rôle en pathologie. Par le Dr. Louis Bory, chef de clinique á la Faculté de Médicine de Paris. Préface du Prof. G.-H. Roger. Paris: Masson et Cie, 1922, pp. 212.

While an enormous amount of work has been devoted to the subject of autolysis and other forms of cellular destruction in their relation to immunity, predisposition, and anaphylaxis, the information is so widely scattered through the journals, many of which are inaccessible to the ordinary reader, that the appearance of this excellent résumé of the phenomena of cellular destruction will be welcome to those interested in the scientific aspect of the problem. The only criticism that can be made is that the author has been somewhat too amiable in his inclusion of rather doubtful investigations, which are as yet not controlled. It is therefore not always possible to judge from the text whether the writer has included the discussion of a given paper merely in order to make his monograph complete, or whether he really believes the statements which he quotes.

ARTERIOSCLEROSIS.

Die Arteriosklerose. By Dr. M. De La Fuente. Dresden: Theodor Steinkopf, 1922. Pp. 32.

This is a reprint in pamphlet form of a series of articles on arteriosclerosis that have been appearing in the *Zentralblatt für Herz und Gefasskrankheiten.* It is designed for the general practitioner and confines itself to an elementary presentation of the physiology, pathology, pathogenesis, symptomatology and treatment of arteriosclerosis. The perusal of such a summary reemphasizes in the mind of the reader our fundamental ignorance of the nature of the degenerative diseases of the bloodvessels.

HIGH FREQUENCY PRACTICE

High Frequency Practice for Practitioners and Students. By Burton Baker Grover, M.D. Illustrated with Ninety-Five Engravings. Kansas City: The Electron Press, 1922. Pp. xii-398.

This book is a response to the desire to break away from empirical pharmacy and an endeavor to establish therapy on the basis of more accurate diagnosis and the more intelligent rationale of physiology and etiological pathology. Although electrotherapy is still in its swaddling clothes and mere buncombe in the hands of many charlatans and quacks, it is nevertheless and undeniably an important branch of therapeutics. The physician owes a knowledge of the indications and proper application of high frequency currents both to the patient and to himself. Throughout this little book, physiology is the guiding principle in therapy. There are many quotations from other authors.

To one interested in this modality, this handbook is of great aid; to one who is not accustomed to resort to this form of treatment it is somewhat of a revelation. The theory and principles of high frequency currents are described in simple and direct language and the entire book is directed along practical lines. It includes chapters on medical and surgical diathermy, blood pressure, pain, and diseases of the eye. The chapter on practice includes the treatment of a great many diseases of various sorts and the author does not hesitate to say when high frequency treatment is of no practical or of doubtful value. A questionnaire is appended for the purpose of enabling the physician to test himself as to his ability to undertake this form of practice. A glossary is added. The author has produced a safe and sane publication on the subject of high frequency practice.

QUARTZ LAMP THERAPY

Anleitung und Indikationen für Bestrahlungen mit der Quarzlampe, "Künstliche Höhensonne." Von Geh. Sanitätsrat Dr. Hugo Bach, Bad Elster i. Sachsen, unter Mitarbeit von Dr. Ferdinand Rohr, Dr. Johannes Keutel, und Dr. Hans Waubke. Mit 19 Abbildungen im Text. Neunte bis elfte umgearbeitete und vermehrte Auflage. Leipzig: Verlag von Curt Kabitzsch, 1922. Pp. 205.

The literature on the subject of quartz lamp therapy is so extensive and is constantly increasing so rapidly that the authors have attempted to compile a monograph on all that is worth knowing on the subject. The various functions of the skin, such as its resorptive capacity, skin respiration, the secretion of sweat and sebum, the regulation of the heating economy of the body and its function as an end organ, must all be considered when applying quartz lamp therapy, which has a correspondingly large field of application. It is indicated in all diseases in which the stimulation of skin activity can be of use to the general organism, especially where the specific action of the ultraviolet rays is effective.

A ninth to eleventh edition of this book speaks for its popularity. Its aim is to include everything that is worth knowing about the quartz lamp and ultraviolet therapy, not as a textbook, but rather as a guide and an introduction to the subject. As there is still much to be learned of this form of treatment, only its practical aspect is considered. The monograph is divided into three sections: the first section treats of the physiological aspect of ultraviolet irradiation and its technic; the second part deals with its indications and therapy in the various groups of diseases, such as internal medicine, surgery, pediatrics, dermatology, gynecology, ophthalmology, otology and laryngology and dentistry; the third section is mainly theoretical and includes also the various apparatus used, with directions for their application. The chapter on the indications for quartz lamp therapy in pediatrics is written by Rohr, that on skin diseases by Keutel, and that on ophthalmology by Waubke. The indications for treatment in each disease are clearly mentioned. A most exhaustive bibliography, including forty-five pages and citations from the latest literature, is appended.

PSYCHOPATHOLOGY

Psychopathologie der Ausnahmezustände und Psychopathologie des Alltags. By Professor Dr. Erwin Stransky.

Zur Psychologie und Psychopathologie der Gegenwartsgeschichte. By Dr. Phil. Gaston Roffenstein. Arbeiten zur angewandten Psychiatrie, vols. III, IV. Bern: Ernst Bircher, 1921. Pp. 35, and VI, 32.

Dr. Stransky expresses in his introduction to the second of these small volumes his appreciation of the discussion which Dr. Roffenstein presents. The reader shares this appreciation of the latter's attempt to bring psychological and psychopathological interpretation into the troubled field of present history. Dr. Stransky's own study is in a somewhat different field. Yet the contrast in the two forms of treatment is an instructive one. Roffenstein has brought to bear a wide range of opinions from sociologists and an array of psychological facts. He lacks, however, a vital appreciation of the dynamic quality which lies in the instinctive life where explanation of sociological facts must be traced back to individual reactions. He attempts to utilize the findings of individual psychology but fails to grasp its place in interpretation and in practical readjustment of social difficulties. He does not manifest sufficient consideration of economic and other external facts which, with the varying attitudes of men toward them, can be appraised and understood only in relation to individual psychology.

Stransky, on the other hand, keeps himself in touch with the dynamic nature of the inner mental life as he seeks to explain exceptional states whether in pronounced psychopathological individuals or among socalled normal personalities. He, too, gathers from a wide range of authorities in the field of psychopathology whom he quotes to support his own view. Yet this he carries through with the force of an illuminating interpretation. He stresses the point that contrasts in behavior, which may amount even to a seeming splitting of the personality, denote not an artificial splitting of the psyche but rather a displacement of the energy activity due to the presence of a new constellation instigated from within or from without. He is one of those who acknowledges psychoanalysis in part but still feels himself repelled by the fancied substitution in psychoanalysis of philosophy for fact. He has not yet discovered that psychoanalysis has only uncovered certain facts which go to explain still more deeply the constellations which manifest themselves in exceptional states and actions as well as the mechanism by which they do this. Both of these small volumes are works of earnest thought and sincere purpose.

NUTRITION OF CHILDREN

Feeding, Diet and the General Care of Children. By Albert J. Bell, A.B., M.D. Philadelphia: F. A. Davis Co., 1923.

It has been rightly said that nutrition is the greatest factor to health. The most important problem that the mother who nurses her own baby has to face is the weaning period. What shall the baby be fed to make him thrive? Dr. Bell in his book greatly lessens this particular problem. Not only does it treat the nursing baby and his diet during and after weaning but includes also the nursing mother, her diet and general care. Both the normal and premature baby are considered. The nutritional value of prescribed foods is simply and clearly given so that it is readily understandable. The book is written in short paragraphs with bold faced captions between paragraphs making it as easy and comprehensible as a mother's own notebook. There are feeding formulas given for the first twenty-four hours of an infant's life until the end of the first year—given with such accuracy that one cannot fail to be impressed with the thoroughness with which the author has handled the subject. The little volume should be enthusiastically recommended to mothers.

THE EXPECTANT MOTHER

Getting Ready to be a Mother. By Carolyn Conant Van Blarcom. New York: The Macmillan Co., 1922.

Geting Ready to Be a Mother is a rather elementary volume dealing with the things the expectant mother should know. The author, in the introduction, stresses the fact that the volume is only valuable as a part of the personal care given the expectant mother by her physician. Much that Nurse Van Blarcom writes is not new to the audience to which she addresses herself but as a handbook of simple straightforward information for the pregnant woman it has its value. The book can be heartily recommended by the physician to the expectant mother. It is cheerful, well illustrated and interesting.

THE SOUL OF A CHILD

Child Psychology. I. The Soul Life of a Child in Its First Four Years. By Vilhelm Rasmussen. New York: Alfred A. Knopf, 1922. Pp. xv, 166.

This book, better than some on the observation of childhood, presents unbiased material directly from child life. Its author is a sympathetic observer with a sincere respect for the child's own position in the world, with also an appreciation of its relation to racial history. Yet there is a lamentable absence of interpretation based upon deeper observation into the dynamic forces at work in a child's mental life. It is to be hoped that the psychology of the unconscious will soon come to the attention of a writer who goes as far and yet stops as far short as this one does.

SKIN DISEASES

Lehrbruch der Hautkrankheiten. Von Professor Dr. Max Joseph. Neunte auflage. Leipzig: Georg Thieme, 1922.

The present edition of this well known publication has been abbreviated to a considerable extent at the request of the publishers for commercial reasons. The author's desire to amplify his eighth edition in all directions would have placed the cost of the work beyond the limits of the consumer's purse. Nevertheless, all of the recent advances have been incorporated.

LIFE WITH A CAPITAL L.

A Room with a View. By E. M. Forster. New York: Alfred A. Knopf, 1922.

Picture Frames. By Thyra Samter Winslow. New York: Alfred A. Knopf, 1923.

These two books, widely different in scope, treatment and style, nevertheless converge upon Life with somewhat of the same feeling. A Room with a View is a novel, the fairly commonplace story of the charming young thing acquiring breadth by foreign travel. All this is preliminary to the commonplace enough next step of finding a suitable husband and settling down to a commonplace life. Only Lucy Honeychurch is chaperoned on her tour through Italy by a neurotic, dependent, spinster cousin, whose angle upon the story sharpens into an ever more scorching focus until the whole thing takes fire under our eyes and we are confronted by that unexpected "something" which happens and which makes Life an adventure worth living.

* * *

Picture Frames is a collection of short stories of lives that are lived somehow, but with the least possible enjoyment. They are disheartening to the born romantic; like *Miss Lulu Bett,* almost too painfully true for those of us who accept a humdrum state of affairs, and ask for nothing better. A good many things happen to the characters in these stories, of course, just the ordinary little things that are all in a day's work. Nobody actually fails; some progress quite favorably. Always there is some perfectly adequate reason why no one is as happy as they thought they were going to be. For the easy custom of making the best of things; compromising; anything for the sake of peace, a home, a husband, or a bank account as the case may be, is ingrained in the American bourgeoisie. Each woman concludes that after all she is better off than the next one, and lets it go at that. Life is a thing tolerated, smugly acquiesced to, and the author of these fine little studies has flayed us unmercifully.

THE GOLDEN BOUGH

The Golden Bough. By Sir J. G. Frazer. In one volume. New York: Macmillan Co., 1922.

By condensing into one volume the salient features of Frazer's masterpiece, he has greatly enlarged his audience. For this we are grateful. The material in its encyclopedic form has hitherto appealed only to specialists in anthropology. It seemed too much of a task for the casual reader, no matter how inquisitive, to work his way through one heavy tome after another. Now he can discover, with the least effort and the greatest possible benefit to himself, that "the world is indeed full of a number of things." Particularly interesting to every physician is the exemplification given of how the primitive mind works. Patients who quickly lapse to primitive levels in the course of certain mental diseases present identical beliefs and pictures, confusing in themselves, but with this background readily understandable.

Again, the relics of primitive belief that we still carry about with us today must appeal to every student of why things are as they are. How our understanding has evolved from magic to religious concepts, from religious to scientific, is a stage of growth that opens vast new fields of thought.

IDYLLS

To Tell You the Truth. By LEONARD MERRICK. New York: E. P. Dutton & Co., 1922.

A man and a girl and a heart interest. Merrick's variations on this essential theme inevitably place his short stories among the season's achievements. They have the idyllic fragrance of one's own most idyllic love affair. Need we say more? Find yourselves pictured as you would like to be, and live with Merrick's very real friends through their curious, palpitating experiences!

BEASTS, MEN, AND GODS

Beasts, Men and Gods. By FERDINAND OSSENDOWSKI, New York: E. P. Dutton & Co., 1922.

A book of narrative which furnishes complete satisfaction to sadistic expression both for the writer and reader. In spite of the incidents being vouched for as coming from an authentic source, this could only be accepted on the basis of the author having deceived himself.

Medicoliterary Notes.

The Medical Woman's Journal for December, 1922, contains two interesting articles on phases of Italian women's relation to medicine. These are The Part of Italian Women in the Struggle Against Venereal Diseases, by Dr. Clelia Lolinni, and The Work of Women Physicians in Italy, by Dr. Carpuppino Ferrari.

* * *

The seventh annual report of the Association for Moral and Social Hygiene in England has just been issued. The association has for its object the abolition of prostitution specially regarded as a legal or tolerated institution. It is held that the attitude toward prostitution by constituted authority as a necessary evil is a hygienic mistake, a social injustice, a moral monstrosity, and a judicial crime.

* * *

The March issue of the *World's Work* contains the first of six articles by Sir Philip Gibbs on Adventures of an International Reporter. This article is the first printing, from the inside, of the famous exposition of Dr. Cook's alleged discovery of the North Pole. Gibbs was the first reporter to interview Dr. Cook, although he had the handicap of starting to Copenhagen a day later than the other press men.

* * *

An interesting study of mental pathology is to be found in the *North American Review* for March in the article by Arnold Whitridge entitled A Backwater of Romanticism. The story is that of Gérard Labrunie, better known as Gérard de Nerval, who was one of the strangest and most interesting figures in French literature during the early half of the nineteenth century.

* * *

The Crisis in Science is the title of an article in the January 13th issue of the *Living Age* by Prof. Adolph von Harnack, of Berlin University. Several reasons are given for the great catastrophe that has overtaken German science; 1, it has become impossible, on account of the enormous expense involved, for Germany to procure foreign scientific books; 2, the cost of paper and printing, and wages have increased to such an extent that German scientific works can no longer be printed; 3, savants are experiencing such difficulties in order to live at all that all their time must go to odd jobs bringing in a little money for the necessities of life; 4, German students are diminishing in number and deteriorating in quality. The writer believes that economic rehabilitation for Germany is the one means of salvation for German science.

* * *

A study of the incidence of serious morbidity among wage earners in *Public Health Reports* for December 29, 1922, shows that an increase in August and September, 1921, of typhoid fever, rheumatism, diseases of the stomach, diarrhea and enteritis, diseases of the skin, and diseases of the bones and organs of locomotion. The rate for all diseases combined dropped in October, but increased again in November. Diseases of the circulatory system tended to diminish in the summer and early fall.

* * *

Dr. Arnold Gesell, professor of child hygiene at Yale University, has written recently for the *New York Times* an article describing the investigations of the mental development of infants, now being carried on at the Yale Psychoclinic. All problems of the health and education of children, according to Dr. Gesell, "involve directly or indirectly the mental hygiene of our preschool population, handicapped, normal, and superior. The diagnostic, supervisory, and advisory functions of our infant welfare stations and child health centres must be gradually extended to include the hygiene of mental development. For all these reasons, the behavior of infancy takes on a new significance, both scientific and social. With time we are likely to become, not less, but more, interested in babies."

* * *

Dr. Robert T. Morris has a most interesting article in the January *Bookman* entitled The Literature of Quackery. Although written in popular style for lay reading, it is scientific in facts and development of argument, and should be of great value as an exposition of numerous kinds of frauds.

* * *

In the April, 1923, issue of *The Yale Review*, W. W. Keen has an interesting article on Louis Pasteur.

* * *

Two plays that are worthy of more than passing comment on Broadway now are *Peer Gynt* at Shubert's Forty-fourth Street Theatre, and *The Adding Machine,* at the Garrick. Both are Theatre Guild productions. One cannot speak too highly in praise of *The Adding Machine.* It is an excellent comedy, witty, unexpectedly droll and very effective throughout.

Peer Gynt has been very well staged with Lee Simonson's best scenic talent and a good supporting company and the only dissatisfaction with the play is that Peer Gynt himself, Joseph Schildkraut, falls short of the part. However, he is probably the best Peer that can be found today and so his deficiency may be overlooked by the general excellence of the play. Both plays are worth while seeing.

Practical Therapeutics

ADOLESCENT GOITRE.*

By Ralph R. Moolten, M. D.,
New York,
Instructor in Surgery, New York Post Graduate Hospital.

The clinical classification of affections of the thyroid gland is always difficult. A useful clinical classification (1) may be sketched as follows: 1. Goitre of adolescence, with hyperthyroidism. 2. Simple goitre, without hyperthyroidism. 3. Goitre of Graves's disease, with hyperthyroidism. 4. Goitre of adenoma, with hyperthyroidism. 5. Goitre of adenoma, without hyperthyroidism. 6. Colloid goitre, without hyperthyroidism. 7. Degenerative and malignant goitres.

Judd states that it is now generally conceded that most forms of goitre require surgical treatment for permanent relief, excepting adolescent goitre, which ordinarily responds to medical management. However, the course of the adolescent goitre varies. Whereas a large proportion subside within a few years, in other patients, the gland continues to undergo hyperplasia. In these latter cases the danger is twofold: in the first place, mechanical pressure symptoms; and, secondly, a thyroid gland that is in any way abnormal is a potential site for the development of a colloid condition, adenomata, Graves's disease, or even, more remotely, malignancy. Hence the early recognition of adolescent goitre is of the greatest importance, if the treatment is to prove not only curative for the present condition, but also prophylactic against a more serious one.

Without a consideration of the anatomical pathology, we have been able to recognize adolescent goitre as a clinical entity. Although in many cases the outstanding feature is a small, diffuse swelling of the neck, there is always a variable degree of definite hyperthyroidism. It is common custom to speak of a goitre that occurs in a young girl near the age of puberty as a physiological enlargement; but when we notice some definite aberration, that does not occur with constancy in the relatively normal individual, we may be reasonably certain of the existence of a disease process; and wherever there is disease, there is need for treatment, or at least for medical supervision.

Goitre of adolescence is not a condition that is often found in the well to do. It is commonest among those who are deprived of the comforts, and, indeed, the necessities of proper living. Youthful workers are particularly prone to be affected—schoolchildren as well as wage earners. To appreciate this fact, it is only necessary to walk along a busy, business thoroughfare in a large city at half past eight in the morning and observe the large number of female workers hurrying to their labors. Half portions of humanity most of them are—poorly nourished, poorly rested; and with a surprisingly large proportion having an enlargement of the neck.

Statistical data, relevant to the incidence of goitre among children in the adolescent age, furnish figures that are absolutely astounding. In April, 1917, under the direction of Kimball and Marine, an examination for thyroid enlargement was made of all the girls from the fifth to the twelfth grades, inclusive, in the public schools of Akron. This work was done with the permission and full support of the superintendent of schools of Akron, Dr. H. V. Hotchkiss. The boys were not examined, because of the relative infrequency of goitre in boys; 3,872 girls were examined, with the following results (2):

Normal thyroids	1688,	or	43.6 per cent.
Slightly enlarged thyroids...........	1931,	or	49.9 per cent.
Moderately enlarged thyroids.......	246,	or	6.3 per cent.
Markedly enlarged thyroids.........	7,	or	0.2 per cent.
Among these there were adenomas..	39,	or	1.0 per cent.

These figures carry their own comment. One gathers an impression of the prevalence of goitre in the young, from the fact that 43.6 per cent. of an average public school community have normal thyroid glands.

ETIOLOGY.

This phase of the subject offers a question that may be met with a great deal of speculation and conjecture; but can not be definitely answered. The accepted view at present is that goitre of adolescence is essentially a compensatory hyperplasia, with a varied disturbance in iodine metabolism. The diminution of iodine content in this type of goitre is inversely proportionate to the degree of hyperplasia. Associated with the hyperplasia of the secreting acini, is an added degree of calcium catabolism, making for a diminution in the total amount of body calcium.

On the other hand, McCarrison considers goitre in general an infectious disease; that the infection is waterborne, and that the organism belongs to the colon group of bacteria. Shepard, a Canadian, holds similar views, and likens the infection to typhoid fever.

The consensus of scientific opinion in this country tends to regard this type of goitre as a deficiency disease. Plummer, Kendall and others have irrefutably shown that iodine is essential to normal thyroid activity; that subiodism produces structural as well as functional changes in the thyroid gland; and that the physiological action produced by thyroid extract is always proportional to the iodine content. In the light of this knowledge one is constrained to accept the view that adolescent goitre is due to a relative lack of iodine; and to accept the infectious theory as an accessory factor.

The rôle of a coexisting focal infection, however, must not be too lightly considered. It occurs with a regularity too great to permit it to be held merely as a coincidence. Moreover, many of our patients show improvement only after a focal infection has been removed, or cleared up. The sites most commonly involved are the tonsils and the teeth; though, not infrequently, the gastrointestinal tract or one of the nasal accessory sinuses is the offending member.

But all young females who have a focal infection do not develop an adolescent goitre. Therefore, we must search farther afield for more remote causative factors, and run the risk of being called empirical, because of our speculation. The factors to be considered fall into two merging groups.

---

*Read before the monthly conference of the Surgical Staff of the New York Post Graduate Hospital, January 18, 1923. From the Surgical Service of Dr. Charles Gordon Heyd, New York Post Graduate Hospital and Medical School.

Group 1.—Essential endocrine dyscrasia: The disturbance may occur primarily in the thyroid gland; or the thyroid gland may be involved because of a general disturbance of endocrine balance.

Group 2.—Essential disturbance of metabolism: Here the trouble can be directly traced to a faulty conduct of life such as:

Errors in nutrition.—Undereating is quite prevalent, not only from economic conditions, but because of some uncorrected physical condition that is responsible for a loss of appetite. Again, in the homes of many who pride themselves on serving a generous table the food has neither a proper caloric content, nor a proper distribution of food elements. A preponderance of animal protein and a decided lack of organic salts seem to be the most frequent mistakes. A common habit is to make luncheon consist of a succession of soda fountain atrocities, which are indubitably palatable, but which certainly do not constitute a properly balanced meal.

Unsatisfactory mental and physical hygiene.—After a confining day, recreation is sought in moving picture houses, and crowded, ill ventilated dance halls. The necessity of sufficient sleep, especially for adolescents, cannot be too strongly emphasized. The sleeping quarters, also, are often grossly improper. A lack of ventilation and an excess of occupants frequently go together. Poor bodily hygiene is a common fault. Too many do not appreciate the value of proper and sufficient bathing.

Neglect of personal functions.—Constipation is a very frequent trouble. Eyestrain is a condition that often goes long uncorrected.

Extraneous elements.—Conditions caused by environment, or situations arising in private life, often produce emotional disturbances. And frequently there is present the handicap of a poor heredity.

These various factors tend to produce a definite, subnormal species of humanity, in whom there is an insufficient amount of thyroid extract thrown into the circulation, to carry on a normal metabolism. In consequence, the only source of thyroid extract—the thyroid gland—is tapped; and in response to the call, the gland becomes overactive and hyperplastic.

In adolescent goitre, therefore, there is a reversal of the mechanism productive of other types of hyperthyroidism. In the various types of thyrotoxicoses, of which Graves's disease is a clinical example, there is an increased metabolism as a result of an overactive thyroid gland. But in adolescent goitre, the thyroid gland is spurred on to an abnormal activity in response to a call for more thyroid extract, on the part of a lagging metabolism, and may express itself in slightly plus values of basal metabolic rates.

DIAGNOSIS.

The diagnosis of adolescent goitre is a comparatively easy matter, if the patient's general makeup is studied; and not a definite syndrome of symptoms is sought. In fact, this type of goitre is not always accompanied by subjective symptoms, and a slight enlargement of the neck is the only evidence of a pathological process. A careful history and a scrutinizing investigation of the patient's mode of living are the important thing. However, several of the commoner symptoms are: 1. Nervousness, which is the most frequent chief complaint. 2. Progressive loss of emotional stability. 3. Lack of power of concentration. 4. General feeling of not being up to par. 5. Susceptibility to infectious diseases. 6. Loss of weight, in about seventy-five per cent. of cases. 7. Asthenia. 8. Dysmenorrhea, or scanty menstruation, especially in those cases which belong primarily in the endocrine group. 9. Hyperpigmentation of skin.

TREATMENT.

The treatment should never be surgical until the goitre is given ample opportunity to subside under proper management; and then, not until after puberty is well established. Operative intervention is especially advisable after this age if the enlargement begins to increase, or has undergone a biotic retrogression into colloid goitre as it most likely will make pressure or it may possibly change its form and become toxic. The points in the proper management of a case are:

1. The removal of all possible foci of infection. The teeth should be x rayed, and a tonsillectomy performed, routinely. The gastrointestinal tract must receive proper attention.

2. The establishment of a proper hygienic régime, both physical and mental. A daily bath is necessary, and this preferably in the morning; though there is no better sleep producer, for those who suffer from insomnia, than a twenty minute immersion in a warm tub, before retiring. These patients often have to be instructed in the proper use of a tooth brush, and other facts about the care of their persons, which they do not learn from their environment. Improper ventilation of sleeping quarters must be corrected. At least eight hours' sleep must be insisted upon, and in addition, if feasible, a short rest in the afternoon. Although plenty of healthful, out of door exercise should be encouraged, the patient must always stop short of fatigue. Too strenuous an application to school work must not be permitted, and this same principle applies to those of other pursuits. Any factors causing mental stress must be removed. An occasional kindly talk will often do much to remove what may appear to be an insurmountable situation to these young patients.

3. The establishment of a suitable diet. This is one with a plentiful caloric value, but with a low protein content. Especially, elements that tend to cause intestinal putrefaction, should be eliminated; and emphasis laid on wholewheat products, coarse vegetables, and other foods that help to promote proper evacuation of the bowels. Milk is an especially valuable adjuvant to the dietary, not only because of its tremendous food value, but also because of its action as an intestinal detoxicant.

4. Medication. In so much as adolescent goitre is a deficiency disease of disturbed iodine metabolism, medication must be directed toward supplying the lacking elements. The normal thyroid contains about three mgm. of iodine per gram of dried glands; twenty-five to thirty mgm. of iodine is the total storage capacity. It is clear, therefore, that only a very small amount of iodine continued over a long period of time, will give optimum results. In the Postgraduate Goitre Clinic, the usual prescription calls

for three to five drops of a saturated solution of sodium iodide, thrice daily. Another splendid preparation is the syrup of the iodide of iron (U. S. P.). This contains not only the necessary iodine, but also iron, a valuable blood tonic. The dose is from ten to thirty drops, three times a day; and for those who are under weight, it is given in a tablespoonful of olive oil. Supplying the whole thyroid gland direct is often an excellent expedient. The initial dose is one tenth of a grain of the dried gland, three times a day. This may be carefully increased, but the patient must be closely watched for any clinical evidence of overdosing. The increased calcium catabolism necessitates calcium feeding. This problem may be taken care of in the feeding, certain raw vegetables and baked potato skin being rich in this element. In addition, the administration of some such preparation as liquor calcis, in dram doses, three times a day, is indicated. As a final word, it is essential that these patients be kept under the closest observation, and frequent examinations made.

1060 Madison Avenue.

The Nature and Management of Hyperthyroidism.—A. B. Cooke (*Western Medical Times,* July, 1922) states that when the thyroid gland produces an excess of thyroxin, tissue destruction progresses faster than tissue regeneration, resulting in hyperthyroidism—a true intoxication. The thyroid gland is a defensive mechanism against emotion and infection; when immunity is overcome, the defense breaks down. The preponderance of hyperthyroidism in women is due to their emotional nature, the stress and strain incident to sex and their greater susceptibility to infection. Many males showed hyperthyroid manifestations during the late war from continued excitement, anxiety, and fear. In response to continued excitation, the thyroid gland undergoes hypertrophy and hyperplasia with a consequent excessive secretion pouring into the circulation. When established, this condition is usually chronic with little tendency to a spontaneous cure.

The hyperthyroidism of toxic adenoma differs from that of Graves's disease only in degree; in the former the symptoms are milder, the basal metabolism is increased less and the danger is less acute. It occurs only in preexisting colloid goitres. It is still undecided just how the adenomatous tissue operates. The author believes that the difference in the two conditions consists in the amount or extent of the thyroid involvement—the whole of one or both lobes of the thyroid gland in Graves's disease and one or more distinctly circumscribed areas in the toxic adenoma.

Every case requires individual treatment, which must take into consideration that the disease also involves every organ of the body, particularly the heart. The medical and hygienic treatment must remain inadequate just as long as patients do not seek early diagnosis and treatment. Medical treatment is of value in the early stages of the disease, but it is slow, long continued and uncertain. Diet and rest are great aids. The author believes that surgery is the treatment of the future, even though the results in the past have not been strikingly successful. Radiation does not cure permanently and must be continued for a long time, while the damage to vital organs may be progressing. X rays or radium treatment is available in tiding over a crisis or in preparation for operation, but they increase the dangers and difficulties of the operation by obliterating the fascial planes and producing adhesions, erratic vascularity and less perfect hemostasis. Certain types of cases, especially toxic adenomas, are markedly refractory to radiotherapy. Where competent surgery is available it is a mistake to depend upon radiation. Surgery is the sheet anchor in the management of this disease, but it is usually deferred too long. Not infrequently a preparatory course of treatment consisting of long rest in bed, icebags to the precordium, sedatives, and other means, are necessary. Unnecessary risk may be avoided by making the first stage of the operation consist of ligation of one or both superior thyroid arteries under local anesthesia. Injections of boiling water or other irritants, as, for example, urea and quinine hydrochloride have been advocated but should be condemned. Recently radium emanations were tried with good results in the form of embedded containers buried in the thyroid. The author prefers ligation to all these procedures. Although radical operations are difficult and sometimes dangerous, the results achieved with them are strikingly good. When the pulse rate is persistently above 100 and the metabolism rate is higher than plus 30, the safest procedure is preliminary ligation.

Congenital Familial Goitre Treated Medically.—J. Bravo Frias (*El Siglo Medico,* March 4, 1922) says the patient and his brothers and sisters form a group of sporadic congenital goitres. Congenital goitre is rare in endemic regions and altogether exceptional among sporadic cases, but instances of both kinds have been reported not only in man, but among animals. Heredity, considered as a general rule of endemic and sporadic goitre, is not present in this case. Syphilis, as it usually occurs, has little influence on pathogeny, although it exists in this instance coincidently with the goitre but seems not to have a causative relation, inasmuch as goitre is present in five brothers and sisters without other specific lesions. The beneficial results obtained by the author in these children from medical treatment led him to advise a resort to organotherapy always when the phenomena of compression are not so severe as to compel a quick resort to surgical measures. The administration of iodides should not be insisted on, for children are frequently intolerant of them.

Management of Toxic Goitre with Radiation.—J. Thompson Stevens (*Canada Lancet,* June, 1922) states that metabolism tests show that at least ninety per cent. of toxic goitres can be cured by proper röntgen therapy. Radiation properly carried out is at present the method of choice in many medical centres. It does not disfigure, it is decidedly less dangerous and the results are at least as good, if not better, than those obtained by any other method. In many cases referred for radiation are the patients too ill for operation or have had operative failures. The results in these cases prove that radiation is the best method in selected cases.

Abstracts from Current Literature

ENDOCRINOLOGY.

The Interstitial Gland.—Leonard Williams (*British Medical Journal,* May 27, 1922) describes the development of the interstitial glands in the two sexes as follows: At the moment of conception, a male and a female element combine to form an entity. These two elements are constantly warring upon each other, each potentially charged with its characteristic interstitial gland which develops early in embryonic life and each one striving for the mastery. When one, say the male element, has definitely gained the victory, a penis and scrotum develop instead of a vagina and uterus; however, this victory is only temporary. In every child there remains a certain number of these antagonistic interstitial gland cells, which are only awaiting an opportunity for action and engaging in a secondary battle at the time of puberty, so that side by side with the secondary male characteristics associated with the male sexual organs, there may be some female secondary characteristics, such as a broad pelvis, a highpitched voice, a female mentality and feminine tastes, a mixture of male and female elements being found in every human being. In most persons, the balance of the male and female elements is in favor of one or the other, producing the distinctively male and female characters, but when they are nicely balanced, the homosexual being is the result.

From these considerations, two questions of social importance arise: 1, the determination of sex in a young embryo, and, 2, the proper attitude of the civilized community toward homosexuality. In regard to the latter, the author maintains that the present law on the subject requires revision, because the affected individual cannot alter or modify his nature any more than he can change the color of his hair: it is a burden cast upon him by external forces over which he has no control. In regard to the other question, he believes that by reinforcing the male element in the embryo by the administration of male interstitial gland to the mother, the victory ought to be in favor of definite maleness in the newborn child and that homosexuality ought to be preventable by the giving of the individual the same extract at the time of puberty. This, however, is not easy because of the presence of antagonists both among the endocrine glands themselves and between the external and internal secretions of the gonads.

The testicle has two sets of glands: those of the seminiferous tubules and the interstitial glands. The former secrete and external secretion and the latter a hormone. These two secretions are in a sense antagonistic. A unilateral ligation of the vas deferens produces a gradual atrophy of the seminal vesicles on the ligated side, which is associated *pari passu,* with a definite hypertrophy of the interstitial elements. This occurrence has been utilized for the purpose of rejuvenating elderly men, resulting in renewed mental and physical vigor at least for a time. Exposure to x rays produces sterility but no loss of sexual appetite, the effect on the testicle being identical with that of the ligation of the vas deferens. Alcohol and tuberculosis seem to exert a similar influence on the testicle.

In regard to the other endocrine glands, the suprarenal is predominantly a male gland; the thyroid is predominantly a female gland, but also has an effect on the male; the pituitary is under the direction of the appropriate interstitial gland, male or female, as the case may be, but seems intimately connected with the ovary; the thymus and pineal glands act as a check upon the gonads, but then there is also the directly opposite action.

The main enemies of man are toxins and his defences are the endocrines, and therefore the national course is to so husband the resources of the endocrines by protecting them from unnecessary poison, that they will be effective in times of stress. The glands in both sexes which are fatigued first are those most closely connected with the gonads—the adrenal in the male and the thyroid in the female. At the menopause, a redressing of the endocrine balance from withdrawal of the ovary causes constitutional disturbance, and at this time, small doses of thyroid (beginning with no more than one grain a day) is indicated.

In males between sixty and seventy years of age, a phenomenon similar to the menopause in women occurs as a result of the accumulation of poisons in the system. The interstitial hypertrophy following certain poisons, is a temporary effort on the part of these glands to repel a chronic toxemia, but they eventually succumb and are accompanied by a senile hypertrophy of the prostate. The results following the removal of the prostate support the view that the prostate is also an antitoxic gland.

Studies in the Transplantation of Organs.—S. Voronoff (*Repertorio de Medicina y Cirugia,* March, 1922) states that among the unicellular organisms which constitute the earliest type of living beings Voronoff tells us that cellular division goes on taking place throughout many generations without a single instance of death occurring, and when from loss of substance a colony undergoes a certain degree of retraction, instead of dying, its members are seen to unite, being rejuvenated and rendered more active by this fusion, and so going on to a new series of divisions. The ameba does not die: it may be destroyed by an enemy or by lack of sustenance, but it knows nothing of physiological death. In higher organisms the cells which approximate nearest to the primitive type are the connective tissue cells and leucocytes, which are also the most universal. A study of old age teaches that the connective tissue cells invade more and more the structure of organs, producing sclerosis, a phenomenon seen alike in the brain and the bones, the arteries and the muscles, the liver and the kidneys. When tissues are grafted they are deprived, while new vessels are forming, of nutrition by means of the circulation: during this period the differentiated cells of the graft atrophy, while the connective tissue cells endure and fill their place when circulation is reestablished. Life, the function of all the organs, is dependent on the activity of the glandular system. There is one gland which supplies a marvellously stimulating energy to all the cells of the body—the interstitial gland. As regards the manifestation of physical and intellectual qualities, a man is worth as much as his interstitial gland. Its internal secretion stimulates the vital energy of every tissue and increases resistance to the invasion of connective tissue which portends the coming on of old age. Since 1917 the author has performed more than a hundred experiments in grafting the testicles of various animals. Inserting the fragments within the tunica vaginalis in the natural location of the testicles affords a better result than when they are placed beneath the skin or the peritoneum. In goats the results attained were amazing. Distinctly senile animals renewed their vigor, appeared younger, recovered from incontinence of urine and from trembling of the limbs, put on flesh, became lively and aggressive, and regained sexual potency. Voronoff comments on the difficulty of obtaining human testicles in any quantity for transplantation, and proposes using those of simians, citing a case in which he successfully transplanted the thyroid gland of a monkey into a boy of fourteen.

Hyperthyroidism.—George R. Murray (*British Medical Journal,* June 10, 1922) divides cases in which hyperthyroidism is a prominent feature into three groups, 1, simple hyperthyroidism; 2, toxic adenoma of the thyroid with hyperthyroidism, and, 3, exophthalmic goitre. In some of the cases there may be dysthyroidism. In simple hyperthyroidism, there is a slight uniform enlargement of the thyroid with symptoms of hyperthyroidism. The early and prompt treatment of these cases is important, as otherwise Graves's disease may develop. Rest in bed for a week or two, or longer if necessary, and three to five minims of Fowler's solution are beneficial. For nervous excitability bromides may be given with arsenic; quinine hydrobromide, three to five grains, is useful with or without arsenic. X ray treatment is more valuable than treatment with drugs. In toxic goitre with hyperthyroidism a goitre either with parenchymatous or . adenoparenchymatous changes may be present for years without producing symptoms, the signs of overactivity then appearing suddenly, usually after a sudden emotional shock or accident, or a prolonged nervous strain. The goitres may or may not increase in size. If the goitre is large, the toxic adenoma should be operated upon as soon as marked symptoms of hyperthyroidism appear. Bilateral partial resection seems to be the best procedure. If operation is not available, the hyperthyroidism should be treated medically.

The treatment of exophthalmic goitre varies according to different authors. The medical treatment entails a stricter régime with prolonged rest in bed. Opinions as to the proper diet vary but further investigations are necessary to ascertain the proper diet. The specific organic preparations have not given satisfactory results. Of drugs, arsenic, bromides, belladonna, convallaria and quinine hydrobromide are the most useful. X ray treatment has proved to be of great value, as it certainly does reduce the activity of the thyroid. In the author's series twenty-five per cent. of the cases were fatal; with rest and medicinal treatment, twenty-five per cent. of the patients recovered and fifty per cent. improved more or less. Of one hundred patients treated with x rays, all are living and seventy-six per cent. either recovered completely or were able to attend to their duties. Radium is unsuitable for very severe or acute cases. In mild cases, operation is unnecessary, but if the trachea is compressed it is essential. In moderate and severe cases the opinion on surgical treatment is divided; in any case, medical treatment should be tried for at least six months and if no improvement results by that time, operation should be considered. The most suitable cases for surgery are those in which the goitre is quite large. The advantages of operation are: 1, the saving of time and the relief from the symptom; 2, the lesser risk of irreparable damage to the heart in the form of chronic myocarditis, and, 3, the complete and rapid recovery in some cases. The disadvantages are: 1, the risk to life; 2, the uncertainty of the final result owing to the difficulty of determining the removal of the proper amount of gland tissue in each case, and, 3, the tendency to recurrence after one year.

The Influence of the Endocrine System on Intraocular Tension.—J. Imre (*Endocrinology,* March, 1922) states that the normal intraocular tension estimated by the tonometer of Schiötz is between fifteen and twenty-six millimetres of mercury pressure, and when the heart stops beating it sinks to eight millimetres. Since 1910 the author has been making systematic observations with the tonometer, particularly in pregnant women. A remarkable case tested by him three years ago was a pregnant woman who showed signs of osteomalacia. Her intraocular tension was less than that of a cadaver, being even less than five millimetres. Among fifty gravid women forty-two had decidedly subnormal tension, two normal, and six high tension. Those with hypotension showed signs of pregnancy in face, hands, skin, and elsewhere, these being regarded as due principally to hyperpituitarism. Those who had hypertension looked unusually fresh and showed no facial signs of pregnancy. Intraocular tension was also found in connection with pituitary tumor. In one such case the pathological process had been arrested by x ray treatment and by a course of thyroid medication. Here tension was perfectly normal. Two untreated patients with osteomalacia had decidedly low eye tension. Of three castrated patients, two were much better as a result and these had normal tension, while the other failed to show improvement and had a subtension of twelve millimetres in both eyes. With the two who were benefited a difference of tension (23 as against 15, and 18 as against 15) remained between the eyes, a remarkable finding, since the rule is that both normal eyes in any given subject have the same tension. Hippel has found that patients with glaucoma give a positive Abderhalden reaction with thyroid and thymus. From his own observations and from the literature the author concludes that the tension is quite labile in goitrous and other thyroid patients. He finds, as a result of his studies, that a disturbance in the balance of the endocrine system causes a disturbance in intraocular tension. When the balance is restored, the intraocular tension approaches or becomes normal. Although we usually have to do with a pluriglandular disturbance, the glands that play the principal rôle in the regulation are the pituitary, thyroid, thymus, and gonads.

Endocrine Adiposity. — William Engelbach (*The Medical Clinics of North America*, July, 1922) evaluates obesity as one of the most important diagnostic signs of endocrine disorders. The increase in weight goes on in spite of a reduction of the diet and other attempts at weight reduction. Clinical evidence shows that the increase in adiposity is associated with a disturbed metabolism of fat. A classical type of obesity is specific for the hypophysis and gonads respectively. The age at which the obesity occurs and its localization and distribution are two aids in the determination of adiposity of the endocrine type.

As to age, there are three divisions: the infantile, the juvenile and the preadult or adult adiposities. The infantile hypothyroid type is characterized by the overweight at birth ,and the tardy eruption of teeth and talking and walking. If the overweight persists after the second year of life, the defect is an insufficiency of the posterior lobe of the pituitary—juvenile adiposity, without mental retardation. Adult adiposity is due to disorder of the pituitary, the thyroid, or the gonads, or a combination of these glands. Insufficiency of the gonads rarely occurs before the age of thirty-four or thirty-five; pituitary or thyroid adiposity may occur during the third decade. The later the advent of the adiposity, the more likely it is to be due to pluriglandular insufficiency and the graver the prognosis.

As to distribution, thyroid adiposity as characterized usually by dorsal hand and supraclavicular paddings and universally distributed adiposity, often transient and evanescent. Pituitary adiposity is located about the hip and shoulder girdles both. Gonad insufficiency shows an absence of adiposity, except in the trochanteric regions until the age of thirty-four or thirty-five. Early castrates show an overgrowth of the long bones and a very marked disproportion between the upper (short) and the lower (long) measurement of the body, with complete absence of subdermal infiltration, excepting the trochanteric padding. True gonad adiposity shows disproportionate mammary enlargement and also an apron of mons veneris shelving and localized trochanteric padding, with diffuse even fulness of the upper thigh down to the knees. If gonad deficiency develops after the age of twenty-five, the osseous disproportion is not seen, as the ossifying centres are then inactive. Pluriglandular obesity shows the individual characteristics of all the various types in the same individual.

The treatment depends upon accurate and early diagnosis of the gland involved or their combined involvement. Treatment should be instituted early while only one gland is affected. The desiccated gland substance should be given in salol coated or creatinin coated capsules to avoid gastric digestion. With the exception of the thyroid preparations, oral treatment is unsatisfactory and hypodermic treatment is indicated. Thyroxin should be given if the oral treatment is impossible in hyperthyroidism. To infants less than six months old, one fiftieth grain of desiccated thyroid is given once daily and gradually increased one fiftieth grain until the toxic effect (as measured by temperature and loss of weight), or until relief is obtained; in adults the criterion is the increased pulse and metabolic rate. In adult pituitary cases, 0.3 c. c. of pituitrin is given and gradually increased 0.06 c. c. per day until the intestinal reaction is produced. In children, 0.06 c. c. or less is given at first; adults receive one to 1.3 c. c. daily by mouth, which is increased 0.12 to 0.18 c. c. daily until the intestinal reaction is obtained; this dose is then increased until the signs of improvement no longer appear. In addition, the entire gland substance, ten to thirty grains, is given by mouth.

Orchic, pineal and pituitary treatments are ineffective in gonad insufficiency in the male. In the female, many good results have been seen with substitution treatment in early and late castrates, menopause cases and in eunuchoid and postoperative females. The administration of the entire ovarian substance is more effective than that of any preparation of its various parts. The author gives 0.6 to 1.2 gm. four to five times daily and ovarian substance hypodermically (one to five or six c. c. daily). In exceptional cases a large intravenous dose gives a more rapid but less prolonged effect. The dosage depends upon the reaction of the patient.

In pluriglandular syndromes, the use of a single gland is advised and after the effect of such treatment is determined, other gland substances may be tried out and added, beginning with the gland producing the most distressing symptomatology. The general dietetic and hydrotherapeutic measures must not be neglected.

Iodine Therapy of Endemic Goitre.—Eugen Bircher (*Schweizerische Medizinische Wochenschrift*, July 20, 1922) attacks the renewed agitation in favor of the use of iodine in goitre. Its use in different ways was condemned in the first half of the nineteenth century, especially when it is used in an uncontrolled manner by the laity, as a patient taking iodine ought to be under the constant care of a physician. In 1920, the author saw thirty-six cases of thyropathy following the use of iodine, even when it was used in very minute doses. In such cases the iodine content of the thyroid gland may reach enormous quantities. Frequently the only remedy is the removal of the iodine depot—thyroidectomy. This is often done too late and the patient succumbs from cardiac insufficiency. At any rate, the physiology and pharmacology of iodine, both in normal and goitrous cases, are so indefinitely defined and the experiences with it have been so contradictory that it seems a dangerous experiment to administer this effective poison to any great extent for a long time, either in the food or otherwise. The iodine prophylaxis, as it is recommended for use in the schools, has not been very convincing.

Iodine Content of the Thyroid Gland.—E. Herzfeld and R. Klinger (*Schweizerische Medizinische Wochenschrift*, July 20, 1922) report on the iodine findings in Zurich in 201 human thyroid glands during the winter, fall, and the spring: forty-five per cent. showed only slight amounts of iodine, four fifths of which contained no iodine at all. This group included 37.5 per cent. with apparently normal thyroids and 41.2 per cent. with pronounced goitre. The cases with an iodine content varying between 0.06 and 0.15 per thousand included 37.5 per cent. normal thyroids to 22.5 per cent. with goitre. The iodine content was greater during the summer than in the winter, possibly owing to the diet of green vegetables, or, the iodine metabolism may be more active in the winter. In thirty-nine thyroids from Holland, there was no appreciable iodine in only twenty-one per cent., as compared with the forty-five per cent. from Switzerland. Although there were some with a medium amount of iodine, there were also those with little or no iodine content. The domestic animals with no appreciable iodine formed 33.24 per cent., and one hundred per cent. of the Swiss cattle, hogs, and dogs tested. The food of the Dutch animals was evidently responsible for the high average of iodine content found in them. The authors state that the iodized table salt is an unconditional necessity in Switzerland, as thirty to fifty per cent. of the population have no iodine or only traces of it in the thyroid a large part of the year.

Iodine Therapy Under Scientific Control.—Max Edwin Bircher (*Schweizer medizinische Wochenschrift,* August 31, 1922) states that the physician should ascertain the condition of the thyroid gland before instituting the iodine treatment of goitre: the symptoms alone do not suffice. There is a reliable method of examination, with which the functional condition of the thyroid may be accurately determined: the basal metabolism is calculated from the consumption of oxygen, the former being completely under the control of the thyroid and every functional disturbance of the thyroid gland must express itself, therefore, in an insufficient control of the basal metabolism. The extent of such a resulting deviation of metabolism from the normal is also a measure for the functioning capacity or weakness of the thyroid. Every increase in basal metabolism contraindicates iodine therapy, but a diminution of the same allows the administration of an amount of iodine which is sufficient to return the metabolism again to the normal condition. Every excess may thus be avoided with this method.

The Thyroid Gland and Iodine in Relation to the Prophylaxis of Goitre.—F. de Quervain (*Schweizerische medizinische Wochenschrift,* August 31, 1922), in his report to the Swiss Goitre Commission, asserts that the renewed proposed methods of goitre prophylaxis, namely, the addition of iodine to the cooking salt in the way it is recommended for practice in the schools and the inhalation of air containing iodine, as practised a long time ago, especially in France, has apparently yielded no definite results: injurious effects were observed even at that time. The nucleus of the question is the proper dose. In adding the iodine to the salt, the dose must be kept below the amount effective for goitre in adults, inasmuch as the important element is the avoidance of goitre in the succeeding generation and the elimination of goitre in adults is too delicate a procedure to allow it to be carried out on so extensive a scale. In the socalled school treatment, one milligram of potassium iodide a week is sufficient. With this amount the effect of the iodine on the other organs, especially on the sexual glands, is not likely to occur in the way it appears following the larger doses used in animal experimentation. All persons showing a hypersusceptibility to iodine (also those at the age of puberty) must be excluded from this treatment, and medical control, the education of the public and the prohibition of the uncontrolled sale of iodine are necessary.

The Iodine Content of the Blood Following Thyroidectomy.—William A. Hudson (*The Journal of Experimental Medicine,* October, 1922) first determined the iodine content of the blood of normal dogs kept under laboratory conditions, and then removed the thyroid of these animals in order to determine whether the iodine content of the blood was changed. The lowest amount of iodine found in normal blood was 0.0029 mg., and the highest 0.0145 mg. The average amount of iodine in the blood of seventeen dogs before the removal of the thyroid was 0.0079 mg. After thyroidectomy the iodine content of the blood was increased. A series of experiments was performed to determine the effect of thyroid feeding on the iodine content of the blood of dogs whose thyroids had been removed. Feeding of fresh thyroid of sheep to thyroidectomized dogs reduced the iodine content of the blood so that it approximated the preoperative level. When the feeding was discontinued the iodine content of the blood was again increased.

Thyrotoxicosis.—J. M. Blackford (*Surgery, Gynecology, and Obstetrics,* February, 1922) emphasizes that: 1. The importance of early diagnosis in order to obtain a cure by surgical removal of a toxic goitre before permanent damage is done the patient. The mortality from removal of nontoxic or mildly toxic cases is almost zero in competent hands, and the net results as satisfactory as can be desired. 2. A badly damaged heart from goitre intoxication does not contraindicate surgery. Practically speaking the cardiac reserve of the patient is nearly always good enough, or can be improved by treatment until good enough, to withstand operation. The bulk of surgical mortality occurs in the badly toxic cases, not in the extreme cardiopaths. I do not remember ever having finally advised against thyroidectomy because of a bad heart, although I have repeatedly undertaken medical treatment for weeks or months before feeling the patient well enough for operation. The postoperative course has shown such remarkable relative cures of cardiac insufficiency as to more than justify the risks undertaken.

Endocrine Insufficiency and Chronic Intestinal Disease.—F. J. Sadler (*Lancet,* May 13, 1922) finds that one tenth grain of the thyroid extract administered once daily gives the best results in the neurasthenic discomforts of the climacterium and that dyspnea on exertion is an early sign of overdosing. Unexpected results were also achieved in arteriosclerosis associated with deafness and also in ovarian tumors. In deficiency edemas it aids by favoring diuresis. It has helped in epilepsy and melancholia in women. The connection between endocrine insufficiency and intestinal intoxication is shown by the improvement following the use of intestinal antiseptics. Ichthyol was found in albuminuria with chronic parenchymatous nephritis. Some chronic noninfectious diseases can be cured or improved by subcutaneous injections of heterogeneous bacillary proteins (Danysz), or by intravenous injections of peptone or heterogeneous bacillary proteins (Gow). The author recommends the use of endocrine gland substances and protein injections as auxiliaries. This is a good field for team work on the part of pathologist, nose and throat surgeon, gynecologist and general practitioner.

Calcium Deficiencies: Their Treatment by Parathyroid.—W. R. Grove and H. W. C. Vines (*British Medical Journal,* May 20, 1922) divided the diseases amenable to parathyroid treatment into: 1, Chronic toxemias, including (a) ulcerative conditions, like varicose ulcer, gastric ulcer, duodenal ulcer, erosion of the cervix uteri and gumma; b, suppurative conditions, like nasal sinusitis, tonsillitis, pyorrhea, otitis media and bacilluria; c, nonsuppurative, like rheumatic diseases, rheumatoid arthritis, osteoarthritis, chronic rheumatism, arteriosclerosis, eczema, chlorosis and sciatica. 2, Conditions of uncertain cause, like menorrhagia, prostatic hypertrophy and urticaria. All these various conditions have two common factors: a chronic toxic state, and a deficiency in the ionic calcium of the serum, due perhaps to a combination of calcium and toxin. Most of the cases reveal a primary septic focus and frequently a parathyroid therapy causes a hidden focus to become apparent by increasing the leucocytic reaction to the attacking micro organism.

Parathyroid glands have a double function: first, regulation of calcium metabolism, and second, to render certain toxic substances harmless. It is possible that continued absorption of toxins may eventually lead to partial parathyroid insufficiency and a resulting disturbance of calcium metabolism, which together lessen the resistance of the tissues, rendering them more liable to secondary septic processes. The authors conclude, therefore, that the ionic calcium of the blood becomes deficient in a chronic toxemia and therefore the septic focus must be sought and treated. Where such a condition exists, healing does not commence until the ionic calcium of the blood approximates the normal figure. Parathyroid therapy rectifies the calcium balance of the blood much more effectively than does the injection of calcium salts. Parathyroid substance is not a specific, but it renders the tissues more capable of performing their normal functions and of combating the effects of toxic processes.

Histological Constitution of the Internal Parathyroids.—F. A. Sanchez (*Revista de Sanidad Militar,* February 1, 1922) says that while the parathyroid glands proper have received much study, little attention has been given in the past to those found within the thyroid glands themselves. The author received for examination a number of such bodies removed from a man of seventy-three years. They existed in both lobes of the thyroid gland, were of medium hard consistency, grayish in color, and easy to detach from the thyroid stroma. From a study of them Sanchez concludes that, 1, internal parathyroids occur in man and correspond in histological structures to those outside the thyroid body; 2, the connective tissue capsule is thick and gives off from its inner surface partitions which anastomose in the form of a net; 3, the epithelial or secreting element consists of compact groups of cuboid cells and follicular groups of prismatic cells ;4, these easily separate into fundamental and chromophile cells; 5, even where the internal parathyroid bodies seem macroscopically separate, the capsule affords only a relative autonomy, and the normal thyroid tissue makes excursions into the interior of the glandule. In general the structure resembles that of other organs of intense secretory activity, the cells containing granules apparently consisting of a phosphorated liquid like lecithin. Phosphoric acid is one of the substances which take an active part in the formation of lecithin, and is also in close relation to calcium metabolism. Calcium is an excitant of the nervous centres and has been found in excess by MacCallum in the blood and urine of animals subjected to extirpation of the parathyroids and even in those of men suffering from tetany. From this may be inferred the possible importance of these tiny glands in investigating the pathogeny of such a disease as tetany.

The Significance of the Comparative Mortality Rates of Parathyroidectomized Wild Norway Rats and Excitable and Nonexcitable Albino Rats.—F. S. Hammett (*Endocrinology,* March, 1922) says that the mortality from tetany following parathyroid extirpation in wild Norway rats was found to be ninety per cent. In gentle albino rats it was thirteen per cent. and in untamed albino rats seventy-nine per cent. The high mortality was regarded as correlated with heightened neuromuscular activity and resultant augmented toxin formation. These reactions were considered dependent on the instincts of flight and pugnacity as manifested in fear and anger. The conclusion is significant in point of our knowledge of tetany. If a function of the parathyroids is to facilitate excretion of guanidin or methyl guanidin, the toxic product of muscle activity, then removal of the parathyroids or interference with their function leaves the toxin to continue circulating in the blood. Consequent high neural and muscle tension are the result in animals where fear maintains a greater excitability, and a lower or chronic toxemia is seen in calm animals, where the muscle tone is low because of the high threshold of the nervous system to exogenous stimulation. Upon this basis, although not fully so explained by him, Crile is accustomed to have his patients undergo a preliminary period before operation of familiarization with the procedure of anesthesia, in which by education fear is lessened.

Acromegalic Syndrome of Late Heredolues.—Gazzolo (*La Presna Medica,* Argentina, 1921, No. 21) states that the study of hereditary syphilis should not be limited, as it has been, to fetal syphilis and to the early manifestations of the affection. Late manifestations possess great importance. Delayed heredolues attacks principally the glands of internal secretion. The author describes an instance of acromegaly in a woman of twenty-eight thought to be due to hereditary syphilis, since she had no other hereditary taint of consequence and the stigmata of heredolues were evident in her, such as high palatal arch, prominent forehead, slightly unequal pupils, rough tibiæ, and the achromic and anectodermic cicatrices on which Castex lays so much stress for their semeiologic value. The age of the patient corresponded not only to that at which the manifestations of acromegaly are seen with most frequency, but to that of the most abundant evidences of delayed hereditary syphilis according to Fournier's statistics. After a course of mercurial treatment the patient improved, her headaches disappearing, and her menstruation, which had been absent two or three months, becoming regular. The Wassermann had been negative, but became positive after the treatment.

Hypopituitarism and Its Treatment.—H. Lisser (*Endocrinology,* January, 1922) gives an enumeration of the hormonic manifestations of hypopituitarism in the osseous system, as dwarfism and acromikria; in subcutaneous tissue, whether as extreme emaciation or extraordinary obesity, the latter usually of the girdle form; in the skin, which becomes dry and smooth as a rule, pale and waxy, inelastic and lifeless, sensitive to slight trauma, and rarely perspires; in the hair and nails, the distribution of the former being more or less nearly that of the opposite sex, the latter showing trophic disturbances; in the generative system, where both the external and internal genitalia are apt to remain infantile and the secondary sex characteristics to fail to appear; in metabolism in the forms of the polyuria and polydipsia of diabetes insipidus, of glycosuria, and of increased carbohydrate tolerance; in the muscular system, as increased strength, endurance, and muscular power, or as muscular weakness and fatigability; in mental and emotional disturbances, among them epilepsy in a few cases and retarded mental development, and possibly in disturbances of temperature, pulse rate, and blood pressure. Lisser groups the signs and symptoms of hypopituitarism in, 1, the Lévi-Lorrain type of pituitary infantilism, manifesting skeletal undergrowth with genital aplasia but without adiposity; 2, the Fröhlich type of dystrophia adiposogenitalis, skeletal undergrowth with genital aplasia and adiposity, and 3, the Neurath-Cushing variety, skeletal overgrowth with genital aplasia and adiposity. Histories of ten cases are given to illustrate these types as they occur both prior to and after adolescence in the male and the female. The etiology of pituitary hypofunction may be found in heredity, in infectious disease, in tumor, trauma, or a foreign body, or in a disturbed function of some other endocrine gland. In the present state of knowledge prognosis is necessarily very uncertain, the best hope existing where diagnosis is early and treatment long continued. Pituitary therapy is at times brilliantly successful, often worth while, and encouraging if persisted in long enough, but sometimes rather disappointing. The great hope of the future lies in the identification and isolation of the actual pituitary hormone or hormones and their manufacture synthetically.

Parathyroid Lesions in Paralysis Agitans.—Victor C. Jacobson (*Albany Medical Annals,* June, 1922) reports a typical case of paralysis agitans which at autopsy showed a marked atrophy and fatty degeneration and infiltration of the parathyroids. A rational interpretation of the parathyroid changes in the light of a possible central nervous lesion would seem to be that the parathyroid lesions may quite as will be primary and the degenerative changes in the brain secondary. The parathyroid glands should be examined in all fatal cases of paralysis agitans, as the muscular rigidity suggests subnormal parathyroid function.

Visual Disorders of Parapituitary Origin.—F. Poyales (*Revista Cubaña de Oftalmologia,* October-December, 1921) states that the anatomical relations of the pituitary gland to the chiasm are so intimate that fifty per cent. of glandular disorders are attended by visual disturbances. Pituitary enlargement produces two classes of visual alterations, functional and organic. Among functional changes occur mononuclear alteration of the field of vision, modifications of the blind spot of Marioette, disturbances of stereoscopic vision, changes in the monocular visual field, and macular symptoms. The organic changes include lesions of the fundus and disturbances of the intrinsic and extrinsic eye muscles. Hemianopsia commonly appears earliest and calls definite attention to increase in the size of the pituitary: Uthoff says it is present in fifty of every hundred cases.

A Case of Acromegalic Gigantism.— Couce and F. Poyales (*La Pediatria Española,* 1920), with comments by J. S. Fernandez (*Revista Cubaña de Oftalmologia,* October-December, 1921), report the case of an eight year old girl who was large at birth and grew rapidly, being when examined as large as a child of twice her age. Among points of special interest at the examination was the small quantity of urine passed in twenty-four hours, leading the authors to believe the deficiency caused by hypertrophy of the anterior pituitary lobe, a lesion which others also have found to have an antidiuretic action. To the same anterior hypertrophy they attribute an increase in blood pressure shown by the patient. In the leucocyte count fourteen per cent. of transitionals were found and five per cent. of eosinophiles, both being in excess of the normal: the authors do not regard the excess as a leucocytosis, but merely as indicating a hyperproduction of young leucocytes in the abundant marrow of unusually large bones. The right eye was found normal, the left completely devoid of vision, a condition ascribed to probable compression of the left optic nerve very near the chiasm by a hypertrophic outgrowth of the anterior pituitary lobe. Extract of the posterior and middle lobe of the pituitary was administered, and amputation by the nasal or subfrontal route of a portion of the anterior lobe was advised.

Radium in Carcinoma of the Breast: A Necessary Preoperative Routine*

By GEORGE STUART WILLIS, M.D.,
New York,
Visiting Physician and Director Radium Department, New York Post-Graduate Medical School and Hospital; Director Radium Department, All Souls Hospital, Morristown, N. J.

Mammary carcinoma comprises more than eleven per cent. of cancer in women, and the present day treatment is early surgical removal. Ewing states in his recent book, *Neoplastic Diseases,* that in 180 A. D. wide dissections and cautery were used in the treatment of carcinoma of the mammary glands. Despite the fact that surgical technic has improved in the last century, statistics show each year an apparent increase in the number of deaths from cancer. Unfortunately, the laity still believes that operative measures offer permanent relief in the great majority of cases. In reality, however, the end results from surgical treatment are still unsatisfactory and often discouraging, and the use of additional therapeutic measures is the only hope for better results in the future.

In more than sixty per cent. of the cases the axillary nodes are palpable at the time the patient comes for examination, and in this type of case Ewing is of the opinion that where operation is performed only one cure in twenty-five may be expected. Willy Meyer states that he has not operated in a single case in which there was no axillary lymph node involvement. In 23.4 per cent. of Halstead's cases with microscopic negative axillæ, death from metastasis occurred. Deaver asserts that approximately one patient in five is relieved by operation and that this would be materially lessened if inoperable cases were included. Surgical statistics, as compiled by American and foreign writers, show that on an average thirty-five per cent. of the patients operated upon for carcinoma of the breast are alive at the end of three years, and twenty-five per cent. at the end of five years.

Handley states that recurrences now are mainly of the intercostal and supraclavicular types. He urges that cases must be received earlier and that some method must be devised to deal successfully with these recurrences. He states further that radium should never be omitted in the treatment of metastasis of the supraclavicular glands. If movable, they are removed and radium applied; if fixed, they are considered inoperable and radium alone is used.

OPERATIVE END RESULTS IN CARCINOMA OF THE BREAST.

Surgeon	*No. of Patients*	*Alive Three Years Per Cent*	*Alive Five Years Per Cent*	*Alive Ten Years Per Cent*
Judd	514	44.7	39.8	32.5
Greenough	320	20.9	..	..

Halstead	210	25.6	..	..
Gassmayer	93	37.7	20.3	..
Franken	75	26.5	..	..
Meyer, Willy	68	32.3	..	..

As to the causes of surgical failures, we may mention, first, the impossibility of removing all microscopic cell nests, irrespective of the ability of the surgeon. We must also remember the wide distribution of the lymphatics of the breast to the axillæ, to the supraclavicular and infraclavicular regions, across the median line to the opposite breast, to the intercostal spaces, to the mediastinum, and over the upper quadrant of the abdomen thereby reaching the liver. Secondly, poor technic, including incomplete operations. We see recurrences frequently where the tumor has been removed leaving the remainder of the breast in sight. Thirdly, manipulation of the breast at the time of operation which may be sufficient to produce implants and metastasis. Francis Carter Wood has shown that massage of the tumors in rats and mice will cause a rapid metastasis to take place. And, lastly, previous to operation the patient may have had many examinations, and the lymphatic extension may have been caused by these procedures.

Radium postoperatively and in recurrences has given results which justify its use, but the most suc-

cessful results will be obtained when radium is used as a routine measure, preoperatively. To understand thoroughly the use of radium preoperatively, the action of radium upon normal and abnormal tissue must be known. The first effect of radium is hyperemia; second, swelling of all the cells including the nuclei; third, degenerative changes, liquefaction, and the absorption of the colloidal material into the circulation; fourth, the formation of stroma and the replacement by fibrous tissue. The preoperative uses of radium are to disintegrate the tumor mass and cell nests and to form fibrous tissue masses which block off the lymphatics and prevent the dissemination of the tumor cells.

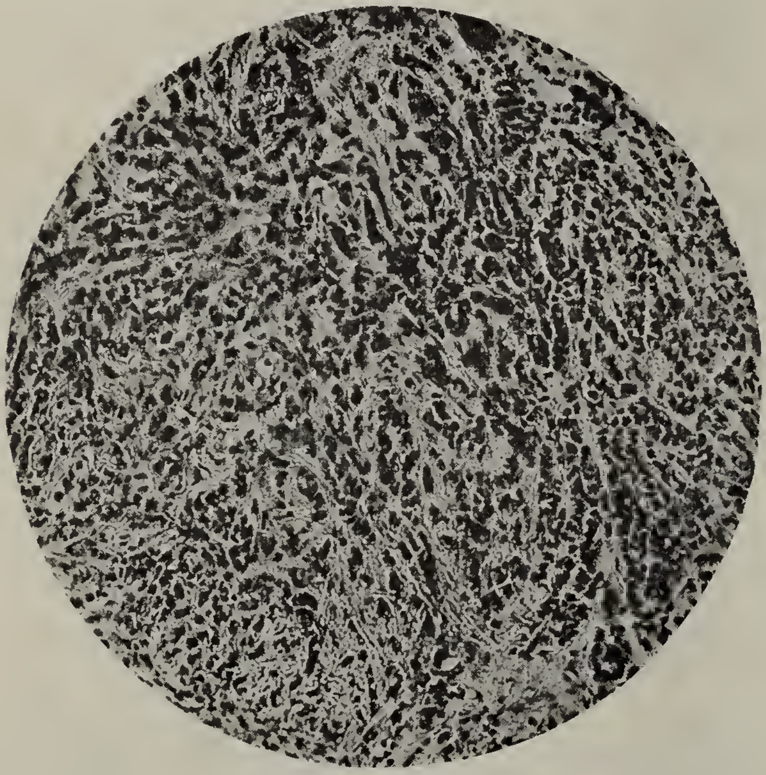

Fig. 1.—Specimen showing typical scirrhous carcinoma before radium application.

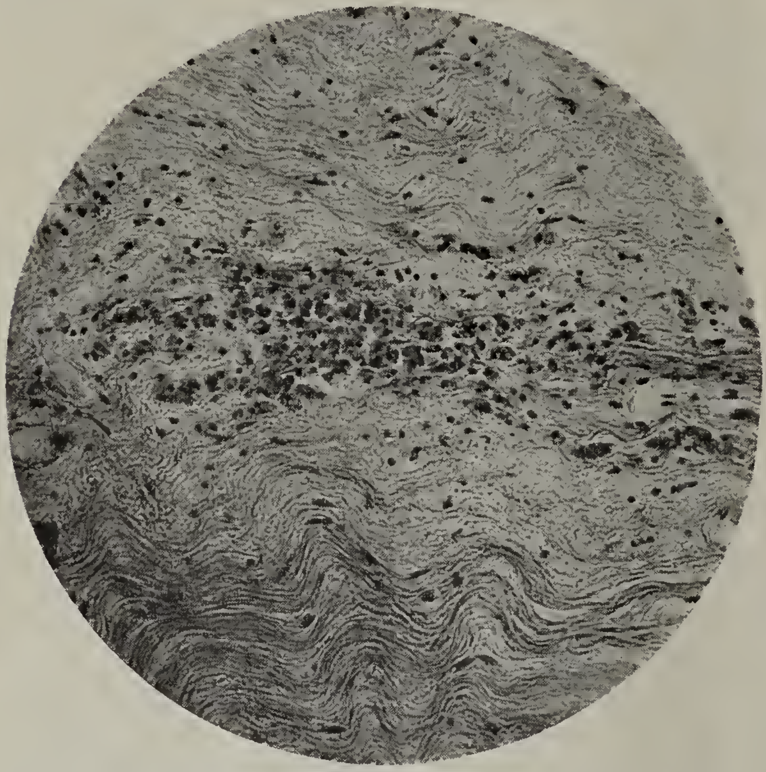

Fig. 3.—Section of degenerative malignant cells completely surrounded by fibrous tissue.

EVOLUTION OF RADIUM TECHNIC.

The early technic of radium application was entirely from a superficial viewpoint. A lead box three by five cm. and two mm. in thickness was used, containing one hundred to two hundred mg. of radium in glass tubes. This box was placed on the growth and remained there for twenty-four hours; the box was then changed to a different position and remained another twenty-four hours. Frequently a patient would receive a total of 35,000 mg. hours in one week.

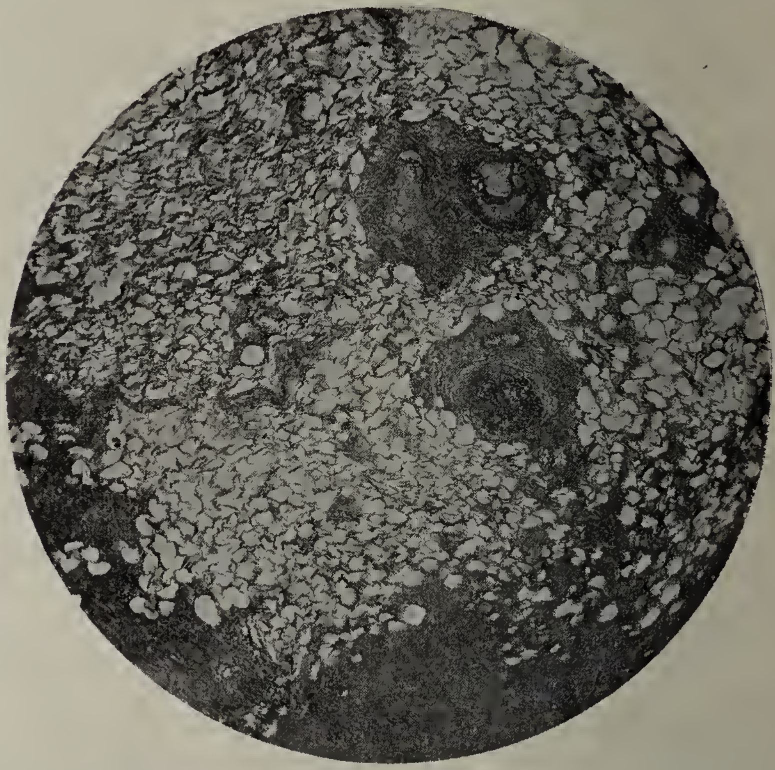

Fig. 2.—Specimen showing degenerative action of radium upon malignancy; resulting fibrous tissue.

It may be interesting to note that the patients treated at this time showed the existence of a radium toxemia, to which I was the first to call attention. This toxemia was so profound in many cases that it was necessary to reduce the dose. The size of the dose was determined by the hemoglobin and the red cell count, which were taken daily. It was also noticed in treating these cases that the resulting destruction of tissue continued for a month, and since that time it had been our habit to give as much

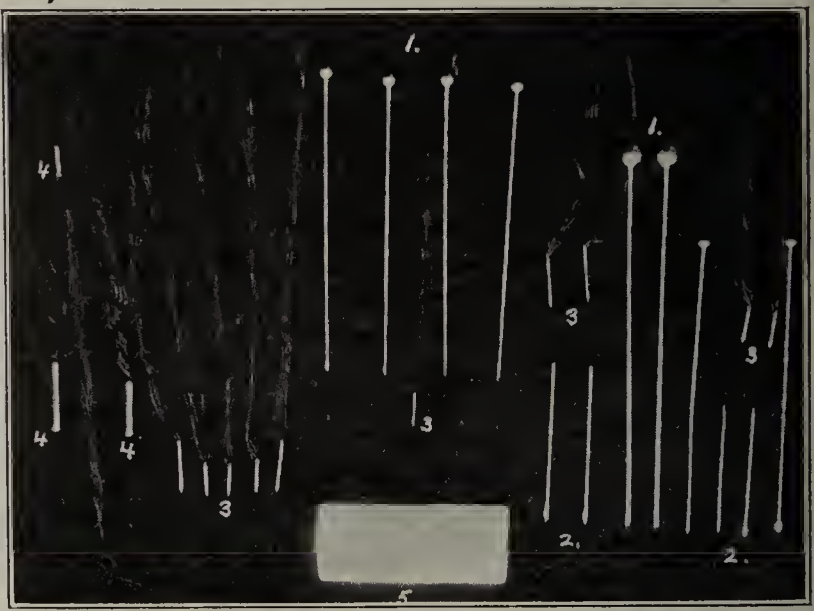

Fig. 4.—1. Transfixion needles, fifteen cm. long, each containing 33.33 mgs. of radium. 2. Radium needles, ten cm. long, each containing twenty-five mgs. of radium. 3. Short needles, each containing five to twelve and one half mgs. of radium. 4. Radium tubes containing thirty mgs., sixty mgs., one hundred mgs. 5. 2.5 cm. block screened with one mm. of lead.

radium, monthly, as the physical condition of the patient could stand. At present, the dose is decided upon after a complete blood count and a urinary analysis have been made. If the kidney is below normal in function a phenolsulphonephthalein test and a chemical blood examination will decide whether the doses will be moderate or large.

Later the introduction of radium sulphate in needles revolutionized radium therapy completely, and the present day efficiency of radium treatment in carcinoma of the breast may be attributed to the possibility of implanting these needles into the growth. These needles, two cm. in length, containing from five to twelve and a half mg. of radium, were inserted into the growth in a stellate form, one cm. apart. Recurrent nodules and large lymph nodes were treated in a like manner. The needles were allowed to remain in place from eight to twenty-four hours depending upon the density of the growth. The lymphatic chains, including the axilla, supraclavicular and infraclavicular regions, and the intercostal lymphatics, were rayed, using six hundred mg. hours to each two inches square.

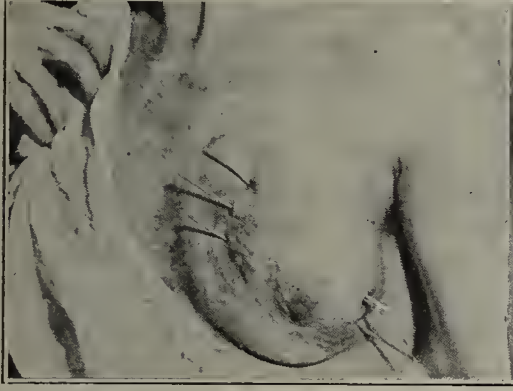

Fig. 5. — Showing three transfixion needles, fifteen cm. long, each containing 33.33 mg. of radium. These are usually left in place for twenty-four hours.

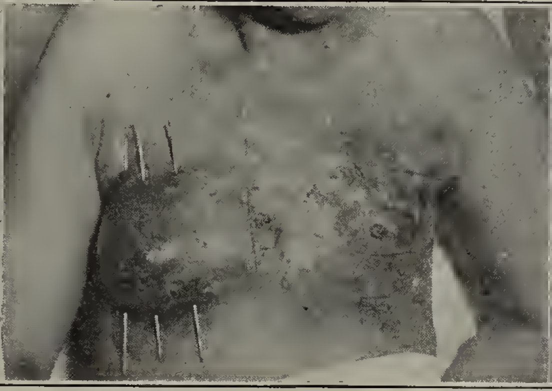

Fig. 6. — Inoperable carcinoma of both breasts. Tumor in left breast treated with radium needles and surface application. The transfixion needles are inserted into the tumor mass of the right breast.

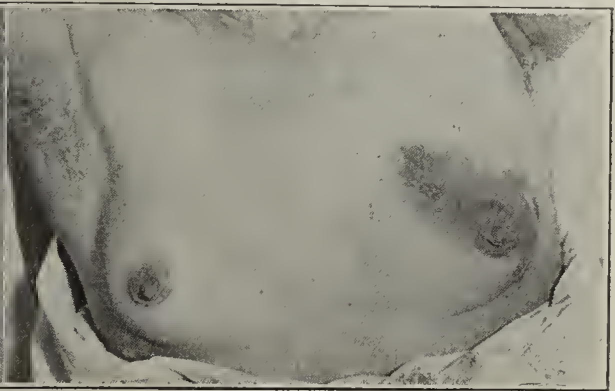

Fig. 7.—Reaction one week after the use of transfixion needles for twenty-four hours. Erythema, swelling and slight ulceration are present.

In the past year my technic has been improved further by the use of a specially constructed needle which I term a transfixion needle, fifteen cm. long, containing 33.33 mgs. of radium. The use of these needles became necessary in order to block off larger areas of tissue and at one treatment ray the entire breast. If it were necessary we reinforced with smaller needles, ten cm. long, containing twenty-five mgs. of radium buried deeply into the initial growth. Gas oxygen anesthesia is usually necessary for the introduction of these needles, and they remain in place for twenty-four hours. On the following day or within a week the surrounding tissue, including all the lymphatics, is thoroughly radiated giving each area 1,000 mg. hours and using the Mayo block.

As a result of our treatment marked erythema is noted over the skin area covering the site of the needles within twenty-four hours. For a week or ten days little change is noted macroscopically. About the end of the second week the breast becomes swollen and tender, and areas of softening are noted. During the third week the breast becomes more swollen and tender, and changes similar to an inflammation are produced. The skin about the needle openings becomes violently red and blistered. The tumor mass becomes very soft or apparently disappears. About the end of the fourth week the breast begins to assume a normal appearance. We frequently note that it may be seven or eight weeks before the breast has contracted and becomes normal, and surgical treatment is not advisable until this stage is reached.

We do not know the best surgical procedure to adopt but at present we feel that in advanced cases the breast should be removed by a simple elliptical incision without wide dissection of the axillary glands unless they are sclerotic. Within six weeks after the operation we advise a complete raying along the scar and surrounding lymphatics.

I feel, personally, that until the dosage which we use has been more definitely proved it is best for the patient to receive a radium treatment once every three months for a year.

REPORT OF CASES.

Case I.—Mrs. C., aged fifty-four, was referred by Dr. Clifford Mills, of Morristown, N. J., in September, 1919. She had had an inoperable carcinoma of the left breast for two years, and for a year and a half had been treated by Christian Science. Examination of the breast revealed the presence of large masses throughout. The axillary and supraclavicular nodes were enlarged. The entire breast was reddened and apparently about to ulcerate. The nipple was markedly retracted. The blood examination showed 3,000,000 red blood cells to the c. c. with a hemoglobin of fifty-five per cent. During September, October, and November, 1919, the patient received several radium treatments; the total was approximately 15,000 mg. hours. In January, 1920, the general condition of the patient showed such marked improvement that the case had become operable. An elliptical incision was made, not disturbing the axillary and supraclavicular regions. The pathological report was adenocarcinoma. The patient received, approximately, five radium treatments, postoperatively, over the various lymphatic areas. Today, March, 1923, the patient is in good physical condition, able to do her housework, with no sign of recurrence.

Case II.—Mrs. M. P. C., aged sixty-eight, was referred by Dr. Charles Gordon Heyd, in November, 1919. She had a tumor in the left breast, three cm. in diameter, and the axillary nodes were involved. On November 10, 1919, a specimen of the tumor was removed for examination. The pathological report was scirrhous carcinoma. During the interval between November 10, 1919, and March 10, 1920, the patient received four radium treatments, a total of 1,600 mg. hours. On March 11, 1920, the breast was removed with a moderate dissection of the axilla. The last radium treatment was given on March 15, 1920, and to date, April, 1923, there is no evidence of recurrence.

CASE III.—Mrs. B. D., aged fifty-five, came for examination on March 2, 1921, presenting a tumor in the right breast, which had been present for one year. This tumor was four cm. in diameter and the axillary glands were palpable. On March 2, 1921, a specimen of the tumor was removed for diagnosis, and four 12.5 mg. needles and one twenty-five mg. needle were inserted into the tumor mass for eight hours. The pathological report of the section taken showed a typical scirrhous carcinoma. The record of radium treatment was as follows:

March 2, 1921, four 12½ mg. needles and one 25 mg. needle		20 hours	1500 mg. hours
March 8, 1921	120 mgs.	20 hours	2400 mg. hours
April 21, 1921	100 mgs.	18 hours	1800 mg. hours
May 26, 1921	operation		
September 29, 1921	120 mgs. 60 mgs.	18 hours 6 hours	1800 mg. hours 360 mg. hours
Total			8160 mg. hours

On May 26, 1921, eighty-five days after the needle application and thirty-five days after the last radium treatment, the breast was amputated.

The pathological report was as follows: Gross: Specimen is a breast without pectoral muscles. Near the nipple is a depressed scar of a former incision. On section a firm mass of cartilaginous consistency is seen close to the nipple about twenty mm. in diameter and continuous with the cutaneous scar. It shows numerous opaque spots about one mm. in diameter on a somewhat translucent background, and there are a few small hemorrhagic spots in it. At one side it is continuous with a rounded area in which there is a small cyst containing disintegrating blood. Microscopic: Two sections were made including the skin, the fibrous tissue and the cavities filled with hemorrhagic material. The epidermis is thin except at the margin of the scar where it is thickened and irregular. The supporting fibrous tissue is dense and hyaline, and partly scar tissue. There are large thin walled and dilated bloodvessels near the surface. Plasma cells ensheath the vessels throughout, and plasma, round and eosinophile cells appear diffusely in the fibrous tissue but chiefly near the surface and near the line of the scars. The fibrous tissue shows a gradual change from viable parts to necrotic tissue, and disintegrating blood fills the cavities. Here one may see occasional shadows suggesting former cystic spaces lined by one layer of large epithelial cells, now necrotic. In the fibrous tissue one searches in vain for mammary gland cells; there are one or two isolated strands of cells resembling compressed ducts or clefts with necrosing walls lined by necrotic epithelium. The carcinoma seen in the first tissue submitted to us cannot be recognized in this specimen. One irregular cleft in the fibrous tissue is about one mm. in diameter and has walls staining pale blue and is lined by flat cells and mildly infiltrated by round, plasma and eosinophile cells. This we interpreted as a needle pathology.

The diagnosis was breast showing scar tissue resulting from radium treatment after excision of carcinoma. To date, March, 1923, the patient is in good physical condition and has had no recurrence.

CASE IV.—Miss M. N., aged fifty years, had had a mass in the right breast for one year. The axillary glands were palpable.

Preoperative radium treatments were given as follows:

August 10, 1920	120 mgs.	24 hours	2880 mg. hours
August 24, 1920	120 mgs.	19 hours	2280 mg. hours
September 22, 1920	120 mgs.	16 hours	1920 mg. hours
Total			7080 mg. hours

On October 9, 1920, radical excision was made. The pathological examination showed marked increase in fibrous tissue, and scattered throughout this connective tissue were clumps of swollen and disintegrated cells. The lymph nodes also showed infiltration with epithelial cells. The pathological diagnosis was scirrhous carcinoma of the breast and metastasis to the lymphatics. On November 19, 1921, 135 mg. of radium were given, postoperatively, for twenty-four hours. At the present date, March, 1923, the patient's physical condition is splendid and there is no evidence of recurrence.

CASE V.—Mrs. N. L., aged sixty, was referred by Dr. Charles Gordon Heyd in December, 1920, She had a mass in the left breast which had been present for one year; the nipple was inverted and the axillary glands were involved. Dr. Heyd considered this case inoperable. Preoperative radium treatments were given as follows:

December 21, 1920	60 mgs.	21 hours	1220 mg. hours
December 23, 1920	120 mgs.	15 hours	1800 mg. hours
December 30, 1920, four 12½ mg. needles (inserted in the growth)		22 hours	1100 mg. hours
Total			4120 mg. hours

On February 14, 1921, a dinner plate excision of the breast was made. There was no axillary dissection. Pathological diagnosis was scirrhous carcinoma of the breast showing extensive necrosis. On February 21, 1921, sixty mg. of radium for sixteen hours were given. On May 2, 1921, the patient returned to the hospital with a swollen gland in the left anterior triangle of the neck which was diagnosed as a malignant lymph gland. The pathological report showed it to be an inflammatory cyst of the thyroid. On August 15, 1921, an axillary dissection was made and the lymph nodes showed densely fibrous tissue diffusely infiltrated by epithelial cells. To the present date there has been no recurrence.

CASE VI.—Mrs. W., aged forty-six, was referred by Dr. Harold Meeker, on February 28, 1922. This patient had had a radical excision of the left breast nine years ago. The existence of the tumor had been known for two and a half years previous to the operation. The pathological report was adenocarcinoma. There was no evidence of recurrence until three months ago. Examination showed a mass, five cm. in diameter at the inner extremity of the scar in the fourth left intercostal space.

X ray examination of the chest revealed the root of the lung displaced two cm. to the right with bulging of the mediastinum at this place. The excursion of the diaphragm on the right side was limited, suggesting mediastinal involvement. Four 12½ mg. needles were inserted into the growth and three 33.33 mg. needles were buried in the surrounding tissue, five cm. apart. On the following day the patient received an external treatment of 120 mgs. over the various lymphatic areas for twenty-four hours.

This case is particularly interesting because of the possibility at the time of operation that cancer nests existed in the intercostal lymphatics and became completely surrounded by fibrous tissue, and it had taken nine years for them to reproduce and extend to deeper structures of the chest.

CASE VII.—M. N., single, cook. Patient consulted me on August 10, 1920, presenting a tumor, the size of a small peach, in the breast involving the nipple. The axillary glands were palpable. Patient had known of the growth for at least one year. The diagnosis was advanced scirrhous carcinoma of the breast. Between August 10th and September 21, 1920, patient received 11,160 mg hours. Operation was performed on October 10, 1920, by Dr. John F. Erdmann. Laboratory report was scirrhous carcinoma with metastasis to axillary glands with fibrous tissue after radium therapy. To date, March, 1923, patient shows no evidence of recurrence and is in splendid condition.

SUMMARY.

1. The progress of surgery in carcinoma of the breast has apparently reached its height and the future will probably show no better results.
2. Radium postoperatively and in recurrences has proved to be of great value.
3. The action of radium upon cancer cells by rendering them incapable of reproduction demands its use as a routine measure preoperatively.

The Toxemic Aspect of Ocular Disease

By PERCY DUNN, F.R.C.S.,
London,
Consulting Ophthalmic Surgeon, West London Hospital.

A toxic condition of the blood affects in varying degree the nutrition of the eye. Seven years ago I dealt with this subject in a paper contributed to the *Lancet* (1). In effect, the object of the paper was to draw attention to the numerous cases of hypothyroidism met with in ophthalmic practice.

Thyroid insufficiency may be translated into failure of the thyroid to protect the body against some source of toxemia. In such cases the gland becomes unequal to the demand made upon its functional activity, and its failure is manifested by numerous signs. It has been common in ophthalmic practice to overlook these signs: to treat the patients on general, because orthodox principles: to ignore the hypothyroid condition and the significance of its presence: to disregard the obvious fact that behind the thyroid insufficiency there must be a cause into which inquiry should be made. It has been the custom, when a toxemic condition is supposed to account for an iridocyclitis, to inquire only into some recognized focus of septic infection, as, for example, the mouth. The possibility that the eye can exhibit infective changes arising from another source of toxemia, in the course of which marked hypothyroidism is manifest, has received but little attention. The fact is, however, that the ciliary body—the blood organ of the eye—is peculiarly responsive to the effects of toxemic foci. A notable example of this is the chronic iridocyclitis known under the name of K. P. This is a disease often of prolonged duration, fluctuating always between improvement and relapse, and proverbially showing a disposition to resist the ordinary methods of orthodox treatment resorted to for its relief. Its notorious intractability to treatment is the measure of the failure to deal with its toxemic source, the existence of which is proved by the signs of thyroid insufficiency present, and the favorable influence upon the course of the disease which thyroid treatment ensures.

Closely allied to the symptoms characterizing K. P. are those accompanying interstitial keratitis in children. Such children are regarded as the subjects of congenital syphilis. But how often does it happen that we are unable to find any evidence elsewhere confirmatory of an active syphilitic taint. Even if a syphilitic origin of the disease be admitted, parenchymatous keratitis cannot be held to be a manifestation of a syphilitic process in activity. Were this to be so, on the contrary, antisyphilitic treatment, which is so commonly resorted to, could scarcely fail to check the course of the disease. General experience, however, has determined that this method of treatment has no influence in controlling the active inflammation present. Moreover, apart from the ocular signs, the small patients are generally, invariably it may be said, the dejected objects of advanced malnutrition and marked anemia. Again, they exhibit many signs characteristic of hypothyroidism.

Finally, the keratitis is secondary to an acute cyclitis, such as might be expected to follow the physical conditions present. That parenchymatous keratitis in children is mainly a toxemic manifestation is supported by the treatment which I came to adopt for its relief. The children were kept in bed, fed on a generous diet, and three grains of thyroid gland were given twice daily. As the physical condition improved, so the intense photophobia and the keratitis subsided. Atropine, with fomentations, was the only local treatment necessary. Thus the toxemia was held in check by the thyroid administration, and gradually normal nutrition came to be reestablished.

There is another disease of the uveal tract, especially destructive in its effects, suggestive also of being associated with a general toxemia. The etiology of the iridoplastic cyclitis, known under the popular unscientific name of sympathetic ophthalmia, still remains a myth. Theories abound as to its origin; nevertheless the problem is no nearer solution than was the case in ancient times. Our forefathers, greatly puzzled by the destructive incidence of the disease, willingly enough, no doubt, accepted the hypothesis that sympathy could be a cause of inflammation. Custom has led to this interpretation being retained. Ophthalmic surgery still continues to be adorned by this particular terminology, which is conceded to be a solecism, but which at the same time is a reflection upon the science of our age. The possibility that the disease may be of toxemic origin has hitherto escaped observation. Although every attempt has so far failed to isolate an organism as the causal agent, it may so be that there is one of a saprophytic type which only becomes virulent when exposed to a toxic environment. The colon bacillus is normally a saprophytic organism: in the intestines it exercises an inhibitory influence upon the putrefactive bacteria of the feces. When, however, intestinal stasis is present, the putrefactive bacteria increase; the colon bacillus becomes pathogenic, and completes the vicious circle of the pervading toxemia. The inference is reasonable that were an organism, such as we have supposed, in an injured eye to become pathogenic owing to this toxemia, its special toxin might be productive of the acute iridoplastic cyclitis in the wounded organ, to be followed subsequently, in the absence of due prophylactic measures, by the involvement of the sound one.

The vulnerability of the ciliary body to toxic infection is sufficient to imperil the recovery of an eye, either after injury or following an intraocular operation. Plastic iridocyclitis has developed even after the strictest antiseptic precautions practised in the course of an operation. The peril of the disease is by these precautions not averted. Natural repair of the tissues cannot be expected with blood infected with toxic products.

All this, of course, may be regarded as pure hypothesis. Nevertheless, it bears closely upon the theme which has been of late impressed upon me, and which it is the main object of this paper to emphasize, namely, the importance of the relationship of intestinal toxemia to ocular disease. What, again, are the facts? Hypothyroidism associated with disease changes is proof of a pervading toxemia. The toxemia is subject to control by thyroid therapy, more or less. But in the case of the toxemia arising from intestinal stasis the most scientific method of treatment must obviously be the sterilization of the putrefactive organisms in the intestines. Until recently no sterilizing process was known; no drug was available which was at once efficient and nontoxic. But all this has now been changed; thanks to the long and patient research work of Ainslie Walker, intestinal disinfection is now an established fact.

By the introduction of the new benzene derivative dimethylmethoxyphenol, the putrefactive organisms are destroyed and the Bacillus coli, owing to their greater powers of resistance (2), under the changed environment, are enabled to cast off their pathogenic virulence and resume their normal character. The significance of this addition to our therapeutic resources suggests the beginning of a new era in the treatment of disease; the fact that the poison trap of the intestines can now be brought under control may prove to be the solution of many hitherto undetermined pathological eye problems.

And not in man only will this advance prove to be effective. Animals also are subject to intestinal toxemia. Calves, for example, are the subject of a disease known as white scour. This apparently corresponds with the summer diarrhea of children, and is attended with similar fatality. Sterilization of the intestines of the affected calves has been found to arrest the disease, and recovery has followed. Some fascination undeniably belongs to the contemplation of the numerous problems of disease regarded from the aspect of intestinal tomexia and its new treatment, and the study of this subject gives promise of yielding valuable clinical results.

Further Observations on Epidemic Encephalitis

*With Especial Reference to Mental Symptoms, Loss of Abdominal Reflexes and Myoclonus**

By I. S. WECHSLER, M.D.,
New York,
Associate in Neurology, Columbia University; Adjunct Attending Neurologist, Mount Sinai Hospital, New York.

So many clinical manifestations of encephalitis have been observed in the past few years during the various epidemics that it would seem superfluous to add further observations. The disease has become practically pandemic in this country, but it has been observed that its course as well as some of its manifestations varied to some extent during the different outbreaks. The present epidemic, which is rather prevalent, has also yielded clinical manifestations which are somewhat different from those observed in the previous epidemics, and it is perhaps worth while to record some of them. It would seem also that a few of the signs and symptoms will bear different interpretation in the light of further experience. Curiously enough, few of the many hundreds of papers which have appeared on the subject, deal with the interpretation of symptoms.

The present epidemic has thus far been characterized mainly by cases in which mental symptoms were predominant. Most of the patients have shown marked psychomotor unrest, insomnia, delirium, usually occupational in character, delusional and hallucinatory trends. In addition, abnormal involuntary movements, especially of the socalled myoclonic variety, were very common. So far the picture has not differed from that previously observed except perhaps in the greater number of fatalities. But contrary to previous experience, many of the patients showed marked diminution or total loss of abdominal reflexes. Of the last twenty-two patients studied, thirteen showed absent abdominal reflexes; three, markedly diminished and sometimes absent; one, unilaterally absent and five present. This loss was particularly noticeable in those patients with outspoken mental symptoms.

---

*From the Neurological Service of Dr. B. Sachs, Mount Sinai Hospital.

It will be recalled that the presence of abdominal reflexes, and more particularly of very lively abdominals, was considered significant of encephalitis. This was true even in cases with probable pyramidal tract involvement as evidenced by an occasional Babinski phenomenon. Indeed, the presence of lively abdominal reflexes was considered sufficiently pathognomonic to weigh the scale in doubtful cases.

This association of psychic symptoms with loss of abdominal reflexes may have some significance. The path of the reflex arc for the abdominals is not definitely known. We do know that the motor pathway runs most likely in the pyramidal tract and the afferent pathway is in the sensory tracts, but it is not known just where the central arc is located. Most people believe that the centre is cortical and probably in the frontal lobe. Now it may be conceded that the mental manifestations are also cortical and probably frontal in origin. The absence of abdominals associated with the psychotic types, without any signs of pyramidal tract involvement, would seem to link the seat of the final arc with the frontal cortex. The objection may be raised that in certain cases at least the loss of abdominals may be accounted for by segmental, root involvement. This is possibly true in some cases although much less commonly than is believed; but in the numerous instances recently observed there was no local radicular involvement, and the two outstanding features were mental symptoms with loss of abdominals.

Myoclonic movements have been observed as acute manifestations of the disease as well as some of its sequelæ, although they were more significant of the former. The explanation commonly given was that they were segmental in origin, and the presence of neuralgic or radicular pain either preceding or accompanying the abnormal involuntary movement was offered as proof of the assertion. It would seem that this explanation is not correct. Certainly no involvement of the sensory root can give such myoclonic movement, nor can any lesion of the anterior root. Involvement of the anterior horn, if at all extensive and destructive, will give no abnormal movement but, on the contrary, paralysis will be noted, such as is seen in poliomyelitis. Socalled irritative lesions of the anterior horn result in fibrillation but not myoclonia. It is well known, however, that lesions of the basal ganglia do give all kinds of abnormal involuntary movements. It is further known that the site of predilection in encephalitis is the midbrain and basal ganglion region. It is therefore more plausible to assume that the myoclonias are due to basal ganglion involvement. Certainly there is not sufficient physiological evidence for the assumption that they are due to root or segmental irritation. The objection that the myoclonias occasionally occur in the region of the local pains is not insuperable; first, because they are more often not associated with any pains, and, second, it may be that the afferent impulses serve merely as stimuli which call forth the myoclonias. The further objection that there is no segmental arrangement in the basal ganglion may be answered that this is not at all definitely known, that there is some evidence of segmental arrangement and finally, that some myoclonias are due to basal ganglion involvement. This may indeed be used as proof of such existence.

However, another explanation suggests itself, namely, that the myoclonic movements are cortical in nature. In this connection I may refer to a patient observed in the present epidemic, who showed myoclonic twitching of the right side of the face and marked mental symptoms. The twitchings were rhythmical and definitely suggested a Jacksonian type. The general rhythm of all myoclonias also suggests a cortical localization.

Herpetic eruptions are perhaps unknown in encephalitis. I have recently observed a patient with typical herpes zoster involving the first to the fourth cervical region on one side. He showed mental symptoms, absent abdominal reflexes, mild myoclonic movements of both upper extremities and bilateral ptosis. This is the only instance in several hundred cases. The absence of herpetic eruptions speaks definitely against sensory ganglion or root involvement. In view of the offered explanation that the myoclonic movements are due to radicular or segmental involvement, as evidenced by the accompanying neuralgias, it is certainly strange that so few patients have shown herpetic eruptions. It is true that an attempt has been made to correlate socalled epidemic herpes zoster with encephalitis and even to isolate a virus, but the results are not convincing. In this connection may be mentioned the attempt to link the intractable pains in encephalitis with thalamic involvement, but it may be definitely stated that true thalamic syndromes have been but rarely encountered, and that most of the pains are probably radicular.

RESPIRATORY SYMPTOMS.

Some writers have called attention recently to a variety of respiratory symptoms in encephalitis which do not merit the air of novelty with which they have been put forth. But a great many different forms of respiratory disturbances have been observed. Many patients have shown typical bulbar breathing and in many instances these cases ended fatally. I have seen typical Cheyne-Stokes breathing in cases of encephalitis. Some patients had attacks of asphyxia, which in one instance, at least, were accompanied by convulsive movements. One patient showed what seemed to be clinically, although this was not proved, involvement of the diaphragm. Rapid respiration, both as an acute manifestation and as a sequel, in the absence of heart and lung involvement, was also observed. Rapid spasmodic breathing suggestive of hysteria, but nevertheless a true sequel of encephalitis, was also encountered. Recently I have observed patients after the acute attack was over, with normal temperature and respiration, and a pulse rate of 100 to 120. This points to a probable dissociation in the involvement of the heart and respiratory centres. Some patients have shown marked cyanosis apparently without signs of involvement either of the heart or lung.

Finally, by way of prognosis, it may be stated that it is most difficult to foretell the outcome in any case of acute encephalitis. Two of the patients mentioned above, one of whom showed Cheyne-Stokes respiration while in deep coma, and the other an acute attack of respiratory failure with cyanosis and convulsion, recovered. On the other hand, some cases end fatally even though there are no alarming cardiac or respiratory symptoms.

To summarize, the present epidemic has been characterized in numerous instances by marked mental symptoms associated with loss of abdominal reflexes; this may be used as clinical evidence that the central arc of the abdominal reflexes is situated in the frontal cortex. The myoclonic movements, which are also so commonly present in patients with mental symptoms, may be said definitely not to be due to low segmental involvement, but either to basal ganglion or cortical lesions. One instance of herpes in encephalitis and one of facial myoclonus, suggestive of a Jacksonian spasm, being extremely rare, are worthy of record. The presence of cyanosis without cardiorespiratory involvement and the dissociation of respiratory and cardiac disturbances, as shown by rapid breathing alone or rapid pulse alone, may also be emphasized.

Etiology of the Neuroses

(Second Communication)

By ALBERT POLON, M.D.,
New York.

INTRODUCTION.

There is but little in the external appearance of neurotic disease that would readily suggest its origin and cause. One could no more tell from the surface configuration alone of a functional disease as to the nature of its production than one could tell the composition and mode of formation of a mineral by merely looking at it. Similarly, a familiarity with the clinical symptoms alone of phthisis would not accord one the knowledge of the specific causative agent and of the intricate structure of the tubercle. In all instances, in order to obtain the information of the genesis of a phenomenon, it must be submitted to an analysis. For each type of phenomena to be investigated there is a correspondingly adequate method of analytical procedure. Its adequacy is determined exclusively by the service it renders and by the results it attains.

Now the specific, if not the only method eminently adapted for the examination of the mode of production of neuroses is the procedure termed psychoanalysis, invented and evolved by Sigmund Freud. Any other procedure, however justifiable it might be in other fields, bearing the designation of psychoanalysis, is misnamed. This misnomer is used much too often with a plagiaristic motive. However, this is by no means the worst feature of such an illegitimacy. The real harm resulting therefrom is the confusion created by the fact that such investigators proceeding with a method which is not psychoanalysis, are obtaining results at variance with those of the regular technic, and are too ready to dispute the analytical findings on the basis of authenticity of facts. Naturally they must fail to attain the necessary insight, to the same degree as a chemist would fail to obtain results were he ignorant of the modern methodology in chemistry or were he to use a faulty technic.

What this psychoanalytical method consists of and how it operates, is beyond the scope of this presentation. It will be considered at a later date. Here we shall treat essentially of the facts and experiences obtained by this method and of the theoretical formulation of the thus obtained empirical data, which would disclose the etiology of the neurosis.

I.

Generally speaking, the material adaptable and usable for our purpose is the mental life of the patient, not only as it presents itself at the time of examination, but what is more important also in its past history from the time of its beginning. This would include all the patient's developmental phases, all his experiences, which would reveal themselves as an interplay between the factors of environment and special constitutional features. The procedure is quite analogous to a cross and a longitudinal section of the individual's life course. Some of its elements will have their greatest connotation in terms of a transverse layer, which embraces a certain time period in all its simultaneous ramifications. Others again will derive significance from their being an end result of a causal chain, the first links of which are rooted way back in the past, in the earliest periods of growth and development.

The material thus obtained shows with a monotonous uniformity two essential characters: A persistence of infantile trends and an abnormal sexual development.

II.

Even a superficial observation of the neurotic leads to the impression that his behavior is essentially that of a child. As a rule he is not selfreliant. He fears being left alone. He is constantly preoccupied with his functions of eating, drinking, defecation, urination, about which he is squeamish, capricious, and often adheres to a special ceremonial. He is pronouncedly egocentric. All things and all persons are mobilized to concern themselves with his ailment. He is likely to show the feeling of inferiority, of being small, not grown up yet; and this distressing feeling has its compensation, in that, inordinate claims are made upon the attention and interest of those about him. Through his disease he may conscript the energies of several or all members of the family. He asks and commands devotion that would not be otherwise his, on the basis that he is helpless as a child. He is quite often impetuous or extremely reticent, shy and bashful as a child would be in the presence of strangers. Usually wrapped up in his family situation he evinces but little interest in the outside world. As a rule he regards life at large as inimical and is intimidated by what he is ready to interpret as threats. His inordinate attachment to members of his immediate family, or an unreasonable quarrelsomeness with them, is pronouncedly childish. The frequent sight of the grown up son catered to by his mother, led by the hand from one clinic or doctor to another, often dressed and washed, and hovered over by her as if he were a helpless infant in the cradle, is as pathetic as it is ludicrous and reminds one of the game of "doctor," that children like to play.

The inability of the neurotic to break away from his parents prevents him from establishing new ties of love and friendship. He cannot commence an independent love life. Hence the persistent remaining under the cover of the old home, exactly as the child must do. Excessive interest in morbid occurrences such as murder, arson, cruelty, is a common childish feature of the neurotic. He reacts to them as if he was participating in them, displaying the anxiety and fears, which children do when they listen to terrible stories. Gullibility, suggestibility, excessive enthusiasm, these marks of the child's mind are consistently found in the nervous patient. He is also incapable of sustained effort. Work and the neurosis rarely agree. There is too much childish shifting of attention.

Striking also is the fact that every neurotic shows an immature sexuality. As stated, the nervous patient lacks the elasticity and initiative in establishing new ties. As a rule his love life is circumscribed, but at all events lacks the full measure of gratification. Many show a pronounced disgust for sexual intercourse. Their love must be a continuation of the pure platonic affection for their parents. The males are frequently impotent, or suffer from ejaculatio precox, the females are often sexually anesthetic (feminine impotence) or suffer from vaginismus, thus representing an immature sexual type. Many masturbate or are engaged in some other autoerotism, in this regard resuming or not abandoning the infantile pathway. In many certain areas of the body play an unusual erogenous rôle. They constantly busy themselves at their mouths and throats, dig at their rectum, investigate their feces, interest themselves in their urine. All this is done with a concentration of attention and a degree of absorption as to suggest that they derive a large measure of erotic gratification from these activities. In this regard one need only recall the great interest children have in their excreta.

In short, without any deeper analysis than merely attentively observing what the neurotic psyche attains for itself by means of the ailment, one cannot escape the impression that this somatically mature person who walks and talks and looks like an adult, is, as far as his neurosis is concerned, in the first place a child in regard to selfpreservation as well as to his procreative function.

III.

There are two maxims prevailing among the laity concerning this paradoxical phenomenon. One is that it is the product of "imagination," and the other that it is engendered by an abnormal function of the genital organs. The first maxim explains the unsympathetic and impatient attitude toward the neurotic, even on the part of the physicians. Since under imagination is understood the conscious activity of the mind—accusations and suspicions are rampant that the neurosis is a simulation and an expression of a malicious will. The second maxim regarding the abnormality of the genitalia has found considerable credence among physicians. Ever since the days of Hippocrates malformations, malpositions, and traumatized conditions of the generative organs have been regarded as the seat of the neurosis.

These two notions have in a dim manner anticipated the truth. It was an intuitive groping in the dark, in a direction which was generally correct. It remained, however, for psychoanalysis to throw light upon the actual situation. While it has confirmed the psychic and the sexual factors as paramount in the production of the neuroses, its contribution is unique in two respects. It has found that the socalled imagination, possessing pathogenic properties is not consciousness, but the unconscious psychic process, and that the sexual disturbance does not lie in the soma but in the sexual instinct.

IV.

The analysis of the patient's mental life—this minute microscopic study of his mind—reveals that in every neurosis there is one or more ideational constellation, an unconscious phantastic structure which contains the motive for the production of the symptoms. The symptoms as a bit of behavior have a meaning and express a purpose in terms of this psychic process. The patient, as it were, is having a twofold orientation in life; one in the light of the demands of reality and expediency, and the other as a result of the phantasy, of which he is not aware. Two masters speaking different languages and having different and often opposing aims rule his mental household.

The influences coming from these sources may flow in parallel streams, each reigning supreme in its field of action. The case of the double personality, or of the conversion hysteric, indifferent to his affliction, is an example in point. Or they may encroach upon each other with the result that the patient is constantly in a state of turmoil, being torn between two contending forces. He cannot wholly obey either out of deference for the other.

Clearly this must lead to a serious impairment of efficiency—hence the anxiety, which always manifests itself wherever an organism is aware of his inadequacy to overcome satisfactorily a difficulty in adjustment.

What is the nature of this disturbing factor, which is not unlike a monkey wrench in the machinery of adaptation? All that has been said in the previous lecture about the unconscious in general fully applies to this unconscious psychic process. Its content is essentially a repetition of trends and interests, which belong to the developmental period of childhood. One may compare the unconscious pathogenic mentality to a volcanic rock, emerging in the midst of a fertile soil. It belongs to another epoch, and has for definite reasons failed to conform to the destiny of the rest of the covered layer. This atavistic stranger retains all the characters of the main stratum of childhood, from which it is a direct continuation. Its dynamic property of influencing conscious thought and inducing motor activity is derived from the forces, which are characteristic of that early period.

It is of interest that the fundamentals of the child's mind have been first studied in the mentality of the neurotic. The information obtained was gathered in fragments of varying configurations. Some of these bits were first found in hysteria, later in compulsion neurosis, also in the material of neurasthenia, and finally others again in what is known as the narcissistic or schizophrenic psychoses.

The reconstruction of these fragments established the fact that there is an infantile sexuality. An unbiased observation of the child since then confirmed directly what was at first derived by implication. One who does not deliberately shut his eyes would not fail to see that the whole of the child's love life is surcharged with the erotic quality, and that the activities it entails are distinctly sexual. This sexuality differs from that of the adult primarily in one respect—it cannot serve the purpose of procreation, but then the kind of gratification sought is the same in both cases.

What is important for our theme of the etiology of the neurosis is the fact that the infantile trends which make up the pathogenic unconscious processes are chiefly of the nature of sexual striving, characteristic of childhood.

V.

The material upon which this statement is based is produced by the patients during the analysis. It consists of reminiscences of early and late infantile sexual experiences.

These involved erotic stimulation of various parts of the body, especially of the erogenic zones such as mouth, rectum, urinary opening, nipples, but also of limbs, fingers, etc.; then again the stimulation may have been principally that of the genitalia. Some of these persisted to a late period, such as thumb sucking and masturbation. This group of activities is characterized as autoerotic.

Then again the erotic striving might have been in connection with an object choice, some person in the immediate environment, such as mother, father, sister, nurse, or governess. Many of the memories are those of gross traumata, such as seduction. Others were of the kind that are tolerated as acceptable forms of affection. Excessive kissing, viewing of the nude body of the child (passive exhibitionism), excessive petting and indulgence, sleeping with adults or bringing the youngster into the bed of the parents. Exposure of adults in the presence of the child or bathing with it. A frequent reminiscence is that of having seen or overheard the coitus of parents or other adults.

In connection with these experiences the child had formed curious infantile birth theories, in which an important rôle was assigned to the rectum. In this phantasy the child revived the evolutionary period, in which the cloaca was the seat of sexual excitation.

The feces had a connotation of a valuable part of the body, often having the meaning of a fetus. Its retention was associated with a pleasurable sensation. Its discharge was a sacrifice, a giving up of a source of gratification, as a token of love and devotion, usually to the mother. A prominent component of the memory of the infantile sex activity is the ambivalence of the child's feeling in his love life. Love and hate coexisted. There was a distinct feature of sadism and its passive form, masochism; also of passive and active exhibitionism. There was frank homosexual as well as incestuous attachment to a parent, or to the brothers and sisters.

Sadism, masochism, passive and active exhibitionism, coprophilia, homosexuality, and other manifestations are spoken of as partial sex impulses, because while in the child they manifest themselves autonomously, in the normal adult they become condensed into the unity of the mature sex impulse. Similarly the undifferentiated love striving to various persons in the household eventually becomes condensed in a strong attachment for one or the other parent. This confining of the love feeling within the limits of a parent personality is spoken of as the Œdipus complex. The partial impulses and the Œpidus complex are always found in the kernel of the neurotic material. But there are several other common complexes.

In addition the patient recalls that in his early life he was markedly egocentric. He had a sense of omnipotence, and a belief in magic. Because of his egocentricity he had an inordinate striving to dominate (the will to power). Frequent elements of the memories of childhood are plans and intentions of murder, arson, cruelty, destruction; also jealousy is a pronounced feature.

All that morality and law have condemned, all that may be regarded as a threat to civilization and social existence is uncovered as the content of the material behind the pathogenic phantasy. And yet, this is what the patient recalls, as layer by layer his amnesia is being overcome. The emerging picture is clearly conclusive evidence that the childhood of the neurotic was polymorphously perverse.

However, the most significant thing about this conglomeration of perversions is that it still exists in the unconscious, and evading the barrier of repression realizes itself in the symptoms of the neurosis. Every feature of the clinical picture, whether a bodily symptom, an abnormal affect, or a compulsive idea can be accounted for in terms of these perversive tendencies.

VI.

Puzzling is the fact that between the days of childhood and the time of breaking out of the neurosis there intervened a period of normality. The perversive tendencies are usually abandoned at about the fifth year of life. There follows, as a rule, a quiescence of all frankly antisocial erotic activity.

Upon an occasion when the tide of sexual desire rises high, such as at puberty, or when there is a difficulty of adjusting his love life, the patient suddenly swings back to the early life period and reenergizes abandoned patterns of infantile sex activity. This process is termed regression. The specific characteristic of this ontogenetic reversion is the fact that it transpires without the patient's awareness. All his conscious and foreconscious mental processes are converging to the one aim: that he may not recognize the nature and true meaning of his abnormal cravings. He is thus spared the pain and shock that might accrue to his better self, but then he becomes neurotic. The neurosis is thus a defense mechanism against the threatened pain from the source of his own infantile impulses.

In the light of this consideration we can note the following steps in the genesis of a neurosis:

1. The step of precipitation of the disease—marked by some difficulty or failure of obtaining gratification in the process of adjustment of the adult love life. In other words a conflict with external reality, which denies the gratification. This acts like a trauma. The trauma may be a single large one, or it may be engendered cumulatively.

2. The second step is that of settling the external conflict by a withdrawal from reality into the domain of phantasy, to the infantile stage of sex activity. This process is termed regression.

3. The third step is the internal conflict between the higher self of the adult personality and the newly revived infantile patterns of sex activity.

Morality, shame, and disgust in the patient prevent him from accepting the stage of regression in all its frankness. He therefore represses. This repression is only in part successful. Its meaning—that is its ideational content, is excluded from consciousness, but the impulsive energy behind the content circumvents repression. As long as it remains disguised in the form of a symptom, it is outside the range of influence from the ego, which induced its repression. The patient cannot possibly by himself obtain insight into the mechanism of its production.

Let us then bear in mind these three etiological factors of the neuroses as we proceed further. They are: 1, External conflict; 2, regression; 3, internal conflict with unsuccessful repression.

VII.

Obviously this does not cover the whole problem. Rarely, if ever, can the external difficulty be adequate enough to be the sole determinant of the regression. The potential neurotic breaks down under conditions in which most people remain fairly normal. Maladjustment of love life is much more common than the neuroses.

The neurotic then is clearly a sensitized subject. In him the external precipitating difficulty plays an anaphylactic rôle. What is the factor which produces this hypersensitiveness?

The answer to this is again to be found in the empirical data of analysis. The childhood history of every neurotic shows one constant feature, namely that his infantile sexuality has been inordinately stimulated. Whereas all children manifest sexual activities, the child who will become the potential neurotic shows an unusual intensity in this regard. There is an overloading of this or that partial impulse, or of this or that complex. This overloading traumatizes the natural course of development. It constitutes a locus minoris resistentiæ, which at the time of its occurrence may not register itself by any loud manifestation, although neuroses in children are not uncommon. But what is a pinhole at the start of growth, becomes a breach in the dam of equipment of adult life. This locus minoris resistentiæ is termed the point of fixation. The libido of the person is fixed at a certain phase of its development. Hence the tendency to regress to it.

The neurotic, fixed upon his early life, constantly harkens to the bygone. He lives in his reminiscences; he is introverted. He has not gotten through with his past experiences and is constantly returning to them. His behavior acquires a meaning in the light of a purpose to settle an unsettled situation, to abreact an unabreacted excitation.

Even in his attitude toward the analyst the patient repeats situations belonging to childhood. He may regard his physician as a father, or an older brother, or someone in former authority, and act and feel in a manner that is understandable only in the light of former experiences.

We must thus add to the three mentioned etiological factors of external conflict, regression and internal conflict, the fourth one—the factor of fixation.

Now the points of fixation have chronological earmarks, that is, they belong to definite time periods in the course of development of the infantile psychosexuality. Thus, some of them belong to the last epoch, namely, anywhere between the fourth and the sixth year of life, at which time all the partial impulses have become submerged and condensed in the primacy of the genital zone. This period coincides with the time when the sexual activity of the child is manifesting itself foremostly about the genital organs on the one hand, and on the other when the child is directing his affection to an object or person other than himself. We call this time the period of completed genital organization, and the libido, the object libido.

Another point of fixation may be anywhere between the second and fourth year of life, at which time the partial impulses still assert themselves autonomously. There is no supremacy of the genital area; the rectum, the mouth, and other areas are sources of excitation. Male and female are not distinguished at this time. The distinction is mainly along lines of activity or passivity. However, even at this early time the libido, as generated by the decentralized impulses, is mainly directed to a person or object other than the child itself. We speak of this time as the period of pregenital organization and the libido as the object libido of pregenital organization. Still another point of fixation is in the time of the first year of life, when the incoherent mass of the sex impulses are functioning mainly with regard to the body of the child itself. The activities are essentially autoerotic. The pleasure is derivable, chiefly from oneself. This period is termed the early period of autoerotism. The psychic processes accompanying it are designated as narcissistic.

This classification of the stages of infantile sexuality are highly schematic. For the purposes of clearness the lines are sharply drawn. Actually the characteristics of organization of the impulses, as well as of what constitutes the object of the libido are gradually merging from one period into the other, carrying over features belonging to an early epoch into a later one. Then again the inceptive rudiments of a later period are always found in an earlier one. Thus, for example, autoerotism is carried over in some measure to the period of object libido. The child at five is still to a certain degree autoerotic, and narcissistic, as manifested by masturbation, or in some children by thumb sucking. On the other hand the child even in the first year of life has considerable libido directed to the mother, especially to the breast and nipple of the mother.

Thus every point of fixation is likely to have the characteristics of all the different stages of development with one predominant feature, which marks by its bulk the particular developmental epoch. The particular morphology of neurosis depends upon the point of fixation to which the regression takes place, but we shall find in every neurosis some marks belonging to another neurotic entity.

VIII.

Let us also bear in mind that this state of ontogenetic atavism is disguised, so that the least likely to know its meaning is the patient himself. Now does it ever happen that this camouflage due to repression is absent? Yes, indeed. The frank perversions and inversions, which are much more common than is generally believed, are instances of regression without repression.

The thing about them of interest to us is that they are sexual cravings which are identical with those of childhood on the one hand, and with the wishes behind the neuroses on the other. The invert and pervert, regressing to a certain point of fixation of their libido, accept the call to the past without any conflict or compunction.

Evidently there must be a definite factor which decides whether there should or should not be a repression, or in other words whether there should be a neurosis or a perversion.

IX.

What is this factor? It is that something in the individual which is generally termed the "I," the ego. It is that part of the personality which is derived from the instinct of selfpreservation, as distinct from the instinct of sex or race preservation. Whereas the sex impulse brings in its wake the premium of pleasuse, the ego instinct's aim is survival. That is why the ego is the seat of reality and expediency, faculties which are coordinated by points of correspondence in the outside world. It is also the centre of logic, judgment, and conscience. Quite the contrary to the unconscious it is guided by the categories of time and space. Through these means it masters environment, erects standards for itself and aims for an adjustment in life, which would enable it to live on in accordance with these standards. In short, it is the organized differentiated self love.

The ego not unlike the sexuality does not arise spontaneously. It is the product of growth and development. Its beginning is present at the very birth. In that primitive state it is entirely selfsufficient and is fused with the primitive sex impulse together constituting autoerotism. As it develops it gradually differentiates itself from its partner. What was at the beginning autoerotism eventually becomes on the one hand the ego, and on the other the libido.

In the exercise of the ego instinct there is, however, always the pleasure and joy which are the remnants of the original autoerotism. In other words the ego retains a good deal of the libido.

The energy of the libido attached to the ego becomes thus available for the building up and maintenance of the high order of organization of the ego. But no matter how high is its development it always retains the original quality of selfsufficiency or self love, termed narcissism. The tendencies of the personality which are directed to the furthering of the ego are therefore spoken of as narcissistic, which conveys the meaning that the libidinous energy of these tendencies is bound up with the ego.

From the original state there is always carried over into the later ego a bit of the primitive selflove, selfadmiration and selfperfection, in the form of an ego ideal, which every person has. The ego ideal together with the functions of conscience, reality, sense of judgment, etc., are termed collectively the ideal ego, thereby suggesting that there are still undifferentiated portions of the ego.

It is this ideal ego which acts as the inhibitor of the sex impulses. In proportion as it checks them and taps their energy for the purpose of its own organization, it grows in importance and comes to occupy the exalted position of being the index of the whole personality, at least for the subject himself. The more free play the sexual impulses have the more primitive is the ego, and vice versa. The degree of self love is in inverse ratio to the degree of love devoted to sexual aims. The quantitative factor, the libido, is transmutable between the two phases of the organism: Ego and sexuality.

However, there is a limitation of the quantity of the libido that the ego may attract onto itself. Beyond a certain limit there results its psychopathic hypertrophy, clinically manifested as egomania. The safer way of checking the sexual strivings is by diverting their energy into a channel which leads to an aim other than sexual gratification, in other words to more acceptable forms of gratification. This disengagement of the sexual impulses from the sexual aim is designated sublimation. The results of this process are all the social service functions, scientific interest, religious and artistic pursuits. The whole range of social living is an expression of its working. The ego permits the sexual impulse to come to the fore provided the form of its manifestation would further the ego.

Now in the instance of the neurosis the number of sublimation outlets for the available libido is inadequate. It therefore reenergizes abandoned channels. As such these channels are not acceptable to the ego, and repression results. What emerges from the repression is essentially the same as in sublimation, namely, the sex striving is robbed of its sexual aim. In this sense the whole of civilization is the product of the process of repression, and is expressive of the balance between impulses which are approved by the ego, and those which are rejected.

Our consideration of the psychology of the ego has taken us somewhat afield. But some apprehension of its elements is essential for the understanding of the genesis of a neurosis.

We must thus add two more important etiological factors to our list, namely, a fairly high level of the ego, and an inadequacy of sublimation for the given quantity of the available libido.

Unfortunately the subject of etiology of the neuroses is much more complex than one would have desired it to be. There is still one more etiological factor, which must be borne in mind, namely, the constitution of the patient.

In the clinical material obtained from the patient time and again one meets cases in which the infantile experience of exercising a partial sex impulse was clearly not excessive. In other words, the infantile trauma was mild. And yet there came about a point of fixation. This peculiarity is explicable only on the basis of heredity.

It is the hereditary factor plus the infantile experience which converge to bring about the point of fixation. These two factors, heredity and accident, vary in each individual case of fixation. In some one, in some the other predominates. The combination of the two is spoken of as the disposition to neuroses.

We have thus arrived at the point where the etiological problem lends itself to a formulation as suggested by Freud. Heredity plus infantile experience constitute the disposition. Disposition plus external difficulty of later life eventuates in neurosis.

In summarizing our discussion up to this point we would say: 1. The neurosis is essentially a repetition of infantile situations. Much of this repetition is betrayed even to a superficial examination of the patient. 2. The seat of the pathological process is in the sexual sphere. 3. The disease is precipitated by an external factor in adult life, inducing a withdrawal from reality into the world of phantasy. 4. This unconscious phantasy is an expression of a regression to an early point of psychosexual development. 5. This particular point of development, termed fixation of the libido, is the resultant of two factors—infantile traumatic experience, and heredity, which constitutes the predisposition. 6. Regression to a point of fixation does not cover the problem of genesis of the neurosis. The phase of the personality termed ego which induces the repression plays an important rôle.

Generally speaking, the neurosis is the result of the mode of distribution of the libido. It depends upon how much the libido is withdrawn from the external world, what point of fixation it regresses to, and how much libido there is in the ego.

In the light of these considerations one finds a criterion for the classification and for the therapeutic approach to the neuroses, which is the topic of the next lecture.

Clinical Significance of the Eosinophilic Cells of the Blood

By A. J. HINKLEMAN, M.D.,
Oklahoma City, Oklahoma.

The eosinophilic cell of the blood, while probably the most important of all the white cells present, owing to the difficulty of obtaining accurate data regarding any of those cells which are usually present only in small numbers, the clinical significance of the eosinophiles has never been fully determined.

Through a careful study of the numerical relationship of the white cells of the blood, by hematinometric means, (1) where absolute accuracy is assured, and by which the differential count is readily made upon a basis of from 3000 to 8000 cells, I have become convinced that the eosinophiles are never normally present in the blood, in the same sense that the lymphocytes and the polymorphonuclear leucocytes are. But they are always in evidence either during disease or unusual activity of certain tissues of the body, or during the direct action upon the blood making organs of certain toxines, poisons or substances that are within themselves chemotactic for this particular cell.

Among more than three thousand differential counts I found no regularity in the presence of the eosinophiles that in any sense could be interpreted as a normal count. I found that the absolute number to the c. mm. of the socalled normal persons vary according to surrounding circumstances.

In the ordinary diseases and inflammatory processes, those tissues or organs that have a direct and open connection with the circulation, and in which infection threatens life, do not liberate positive chemotactic elements, when affected, that act upon the blood making organs to stimulate increased production of the eosinophilic cells. The eosinophiles, at the same time, are attracted to the inflamed area as much as the other granular cells are; as a consequence of which the tendency is to take the eosinophiles entirely out of the circulation.

On the other hand, those tissues or organs of the body in which the route to the circulation is less direct and open, and in which diseases and inflammations are always more passive and never directly threaten the patient's life, do liberate positive chemotactic elements, that stimulate the blood making organs to an increased production of the eosinophiles, while there is a correspondingly increased demand. As a consequence of this process, the usual eosinophile count for the person remains unaffected or may be increased. A classification of the tissues and organs in this respect may be made as follows:

Eosinophilic Positive	*Eosinophilic Negative*
Skin	Appendix
Subcutaneous tissues	Intestinal tract
Muscles	Peritoneum
Bones	Pericardium
Urethra	Uterine cavity
Bladder	Liver
Kidneys	Endocardium
Ovaries	Pleura
Fallopian tubes	Gallbladder
Prostate gland	Respiratory tract

In uncomplicated diseases and inflammations of the eosinophilic positive tissues, the eosinophiles of the blood will invariably be found to constitute from 0.5 per cent. to seven per cent. of the total white count, while in uncomplicated diseases of the eosinophilic negative tissues, they seldom reach 0.1 per cent. of the total count.

In the case of acute appendicitis, peritonitis and any other of those severe infections that may readily end fatal the eosinophiles are usually found entirely absent among three thousand cells, while in uncomplicated cases of pelvic infection involving either the ovaries or fallopian tubes, they are invariably present among this number of cells and may constitute as high as seven per cent. of the count.

In such conditions as furunculosis, rheumatism, trichinosis, osteomyelitis, gonorrhea, cystitis, renal calculus and diseases of the prostate gland, the eosinophiles are always strikingly present. In the case of syphilis, sarcoma and carcinomatous conditions, the presence or absence of the eosinophiles from the circulation depends upon the tissues envolved.

EOSINOPHILIC POSITIVE TOXINES.

The foregoing refers simply to the manner in which the eosinophiles are affected by the products originating in inflamed or diseased tissues regardless of the cause. Certain elements, however, in the etiology of diseases, such as the products of certain intestinal parasites, the tubercle bacillus and whatever the toxin or poison concerned in bronchial asthma is, are of course, eosinophilic positive within themselves and produce an increase of the eosinophiles regardless of source in cases of this class the increase is usually distinctly pronounced.

CONCLUSION.

1. The eosinophilic cells of the blood are present as a result of the action of extrinsic forces upon certain tissues that liberate eosinophilic positive chemotactic elements into the circulation, or as a result of direct action upon the blood making organs of eosinophilic positive, chemotactic elements contained in bacteria, parasites and unknown toxins or poisons.
2. Those tissues or organs of the body in which the route to the circulation is direct and open, and in which infection may readily prove fatal, constitute the eosinophilic negative tissues.
3. Those tissues or organs, on the other hand, in which the route to the circulation is less direct and open, and in which an infection is less likely to prove fatal, constitute the eosinophilic positive tissues.
4. Eosinophilic positive chemotactic elements in the way of products from bacteria, parasites and unknown toxines and poisons produce a rise of the eosinophile cells of the blood regardless of source.

The Influence of the Local Blood Supply on Crisis and Lysis in Pneumonia*

By GEORGE G. ORNSTEIN, M.D.,
and A. BRAUNSTEIN, M.D.,
New. York.

From the vast accumulation of literature one can readily see that there is no more interesting problem for investigation among the acute infectious diseases than acute lobar pneumonia. What has particularly attracted the attention of clinicians, and in spite of the great amount of investigation, remains unsatisfactorily solved, is that remarkable phenomenon called the crisis. The interesting and practicable question to determine is the nature of the changes occurring in the balance between the invading organism and the invaded host. The abrupt and radical changes that occur in the condition of the patient from a state of extreme hazard and distress to one of safety and comfort indicate that some profound change must have taken place in this balance. To describe the actual nature of the changes taking place at this time is the purpose of this paper.

PATHOLOGY.

Inasmuch as the stereotyped textbook description of the pathology of the pneumonic lung in its three stages is known, we feel quite justified in omitting this phase of the subject. We believe, however, that the factor of prime importance is the pathology occurring in the circulatory portion of the affected area, the changes occurring in the alveolar structures themselves being actually of only secondary importance. Osler, Adami and McCrae, and Delafield and Prudden state that in the stages of congestion and red hepatization, however, the circulation in the capillaries may be interfered with by the hyperemia, and by the compression of these capillaries due to the alveolar exudate and contents, the vessels are still pervious to the circulation of blood. On the other hand, in our opinion, the all important circulatory change occurs in the transition to the stage of gray hepatization.

Kline and Winternitz (1), in 1913, in their attempt to discover the fate of polymorphonuclear leucocytes, took up the study of changes in the circulation in pneumonic areas. Before discussing the results of their work, it may be well to review the previous and prevalent opinions of the changes occurring when red hepatization becomes gray hepatization. The anemic appearance of the latter has been attributed to various causes. The oftmentioned change is the loss of the red blood corpuscles in the alveoli where it is true they are many in number and well preserved in the red stage, both in outline and in their hemoglobin content, whereas in the gray stage they are scarcely to be seen. Again, in the latter picture, there is visible a recent marked infiltration with, and packing by, polymorphonuclear leucocytes, their number and compactness in the alveoli being the factor held to give the grayish color to this stage. Aufrecht (2) says that the exclusive cause of this transition was the substitution of white for red blood cells. The conclusion was soon widely accepted that the progressive pallor after engorgement and red hepatization was produced by the ever increasing number of leucocytes in the exudate, and partly by the compression of the walls of the capillaries by the ever increasing exudate.

Kline and Winternitz, in their experiments, employed rabbits and the lungs at autopsy of human beings dead of pneumonia. Having injected a normal rabbit intravenously with trypan blue and then infecting it with virulent cultures of pneumococci, upon killing the animals, they found both lungs uniformly stained with the dye. They then first infected rabbits with similar cultures of pneumococci, and on injecting the dye after such infection found that that part of the pneumonic area, that had failed to take up the dye, was readily demarcated from the remaining normal portions of the lungs in the gross, and failed microscopically to show any proportionate staining. By injecting human pneumonic lungs at autopsy by the pulmonary vessels, and employing the same dyes, they found that again the dyes had failed to penetrate the consolidated areas, the normal areas having uniformly taken up the blue color. On section, all such nonstained areas were found to contain capillaries that were plugged with fibrin and thrombi. To show that the impenetrability of the dye was not due to intraalveolar pressure produced by the exudate present, one lung of a rabbit was distended with air, by means of a catheter in a bronchus, under a pressure of 120 mm. of mercury, and injection of both lungs by the vessels with the dye gave uniform staining and coloration throughout both lungs. In other rabbits, after the administration of phosphorus and chloroform to decrease the ability of the blood to deposit its fibrin, the animals were infected with pneumococci. The dye was then injected intravenously. Here the lungs were again uniformly dyed, as well as the pneumonic areas. The conclusion was then apparent to these workers that fibrin thrombi in the capillaries of the consolidated areas were responsible for the obstruction to the circulation. The conclusion is therefore also certain that, in the transition from red to gray hepatization, the marked and constant causative factor is this impairment to local circulation, the blood stream no longer being able with its serum to carry in dyes into the consolidated lung tissue. Other workers, Ribbert (3) and Pratt (4) have taken note of these thrombi in the capillaries, but they interpreted them as being possibly due to agonal or postmortem changes.

---

*From the Vanderbilt Clinic, College of Physicians and Surgeons, Columbia University, New York.

With regard to the lymphatics in these areas, Pratt has stated that in the stage of gray hepatization there is occlusion of their lumina by a proliferation of the endothelial cells, the vessels becoming distended with cells, serum, and fibrin.

TOXEMIA.

The nature of the substances produced by the growth of the pneumococcus has for many years caused wide discussion and much speculation. The oldest theory, and probably the one most adhered to of recent years, has been Pfeiffer's endotoxin theory, which presupposes that the bacterial cell bodies first undergo a dissolution, such proteolysis setting free various poisonous protein fractions which cause the toxemia of the disease. Rosenow, Neufeld and Dold, Cole (5), and others were able to produce symptoms analogous to anaphylactic shock in animals by the use of cultures of pneumococci digested in sodium cholate and by the autolyzed bodies of pneumococci in salt solution. The use of such autolyzed preparations sometimes gave pictures of anaphylactic shock, but at other times the effects are very slight. On the basis of dissolution of the bacterial cell bodies as the cause of symptoms in pneumonia, it would be natural to expect that, following the crisis, there ought to be an aggravated clinical picture, since at this time resolution of the pneumonic area causes widespread dissolution of the bacteria present as well as of the exudate. We know such an aggravation of the clinical picture does not occur. Anaphylaxis and its production are not the usual causative factors in the toxemia. Using digested masses of any bacterium will produce the picture of shock, the explanation then being that of primary protein sensitization and secondary anaphylaxis.

Douchez and Avery (6) attempting to find a more plausible explanation for the manifestations in pneumonia, were able to demonstrate in 1917, that young fresh cultures of pneumococci produced, during their early growth, a soluble substance which could be precipitated by homologous immune serum. This same substance was soon demonstrated by them in the blood stream and urine of experimentally infected animals, and then in humans suffering from pneumonia. This substance soluble in salt solution could not, in the fresh cultures, have been derived from old autolyzed dead bacteria since fresh young cultures were used. It could not have been produced by dissolution of cell bodies in the new growths since the substance was isolated during the first twenty-four hours of growth. During this time the growth therefore in the medium was in direct geometric proportion, by actual count, with very little or no cell death.

Though this work does not definitely prove that this soluble substance is the actual cause of the pneumonic toxemia, it brings us a step further toward considering a soluble toxin as the factor in the symptomatology.

The authors feel that they can rule out the dissolution theory as the possible cause of the toxemia. This can be assumed when we realize that during the stage of resolution, as mentioned, there is the greatest absorption of the products of digestion of the pneumococci. If the toxemia were due to absorption of such products, we ought to expect symptoms at this period. Inasmuch as there is toxemia during the period that the pneumonic area is vascular (stages of congestion and red hepatization) it may be assumed that the substances causing the toxemia are soluble and are absorbed into the circulation.

Bearing in mind the changes in the circulation as outlined, and the possibility of a soluble toxin causing the toxemia, we undertook the study of a series of protocols on autopsies of cases of pneumonia. If the pathology of the circulation was correct, gray hepatization should always be found accompanied by either of the stages of congestion or red hepatization at autopsy. In other words, if the latter two stages terminated in gray hepatization, the patient should have recovered in the absence of another lethal factor. Death supervenes only while some portion of either lung reveals either of the stages of congestion or red hepatization. If the original area has become gray, it will always be found that another area, or other areas, have become freshly involved.

Through the courtesy of Dr. Douglas Symmers, director of the Bellevue Hospital Pathological Laboratories, who kindly placed the protocols of the hospital at our disposal, we are able to report the findings in eighty-seven autopsies of lobar pneumonia.

Selection of cases was made with certain restrictions in mind. The cases selected were those of lobar pneumonia in which it was the sole cause of death so far as we are able to determine. No cases of bronchopneumonia were tabulated in our series. Cases of lobar pneumonia with marked hydrothorax were omitted, as well as frank cases where there were found at autopsy other conditions lethal in themselves, such as coronary atherosis, empyema, a complicating pneumococcic meningitis, and so forth.*

1. Of eighty-seven autopsies of lobar pneumonia, there were thirteen in which an area of congestion was found, or sixteen per cent.

2. There were seventy-two in which an area of red hepatization was found, or eighty-three per cent.

3. There were eighty-five in which an area of either congestion or red hepatization was found, or 97.7 per cent.

4. There were two cases in which the stage of gray hepatization occurred, or 2.3 per cent.

In the cases with gray hepatization, one entire lung was thus involved in each case. It is therefore possible that areas of congestion or red hepatization may have been present but not noted in the protocol because of the preponderating lesion on one side.

SYMPTOMATOLOGY.

As in any other disease, the symptomatology in pneumonia has been attributed to a profound toxemia. The symptomatology of pneumonia is well known to us all. Our object in this paper will be to discuss only the sudden onset and sudden cessation of symptoms in the light of the above pathology. From the onset of the disease the temperature is marked by a sudden rise to its maximum, and continues at that level with more or less variation. This state continues for a number of days when it may abruptly fall. This fall of temperature, with its cessation of all discomfort, is called the crisis. This phenomenon has been the subject of much discussion. It has been generally agreed that the crisis in pneumonia is produced by a sudden increase in the defenses of the body. The immunity to pneumonia in man, it has also been agreed, is slight at best and only of short duration. The only antibodies demonstable are those of the secondary order—bacteriotropins, which alter the bacteria so as to be more easily susceptible to phagocytes; and those antibodies, agglutinins and precipitins, which are of diagnostic value only. The work of many experimenters, especially that of Neufeld, could not prove that bacteriotropins act. Rosenow (7) found a low opsonic index at the start with a slight rise at the crisis. Clough (8), discussing the results of this work, believed its significance questionable even if true. Certainly in the face of the indecisive results of the above researches and those of other workers, the mechanism of the crisis cannot be entirely explained on the basis of an immunological reaction.

Immediately following the crisis there is a comparatively sudden fall in the various manifestations of the disease, temperature, pulse, and respirations falling to normal, with a marked change from discomfort to comfort and refreshing sleep. How can such a sudden alteration in the picture occur? It can occur only with a subsequent discontinuation of absorption of the substances causing the toxemia. Moreover, such a discontinuance can be explained in only one way—a mechanical interference with the circulation in the pneumonic area. This is brought about by the formation of fibrinous plugs and thrombi in the bloodvessels in the involved area, making this area avascular.

RESOLUTION.

The exudate in pneumonic lung tissue has been shown to be proteolytic, even though sterile of pneumococci, and hence contains a ferment which has been called trypsin (9). Such proteolytic action can be controlled if serum is added to the exudate and the substance to be digested. The blood serum, it has been concluded, contains a controlling ferment, antitrypsin. In the avascular period resolution proceeds. There is digestion of the exudate and of the alveolar contents including the pneumococci; and this process, it has been shown, takes place only when the disturbance in the trypsin-antitrypsin balance is such that it gives the trypsin a free hand. The serum with its antitrypsin is almost entirely absent from the pneumonic area during early resolution, and such an absence can occur only when the circulation is shut off in that area. Enough seepage of serum occurs, however, to prevent destruction of the alveolar walls. With the complete absence of serum, local necrosis takes place. With the free access of serum, that is, with an insufficient interference of the circulation, delayed resolution is the result. As resolution proceeds the thrombi and fibrinous plugs in the vessels are also attacked by the trypsin, and the circulation is gradually reestablished.

SUMMARY.

Crisis is the result of a mechanical interference with the circulation in the pneumonia area, brought about by the formation of fibrinous plugs and thrombi in the bloodvessels in the involved area. With the cessation of circulation, absorption of toxic substances from the pneumonic area ceases and the phenomenon termed crisis occurs. Lysis is a more gradual mechanical interference with the circulation in the pneumonic area.

Symptoms are manifest from the time of the inception of the disease until the pneumonic area becomes avascular.

The toxemia is probably caused by a soluble substance absorbed into the circulation.

The termination of a pneumonic process is not only caused by an immunological but also by a mechanical phenomenon.

Etiology and Pathogenesis of Anal Pruritus and Pruritus Ani*

By J. F. MONTAGUE, M.D.,
New York,
Rectal Clinic at University and Bellevue Hospital Medical College.

Disregarding for the time being the question of whether we are dealing with a symptom or a disease and proceeding under the assumption that this condition is an actuality and not merely an hallucination existing only in the patient's mind, we find, upon consideration, that we are dealing with a certain sensation of irritation which is projected in consciousness to a definite area of the body. This area consists of the terminal three quarter inch of the anal canal, the mucocutaneous margin and an elliptical area of perianal skin which extends two and three quarter inches anteriorly and posteriorly from the centre of the anal orifice and two inches laterally on both sides from the same point. This is the area in which or throughout which the conditions under discussion play havoc and inasmuch as the symptoms are clinically uniform throughout this zone I am going to refer to it, for the sake of convenience, as the pruritic zone.

We have then a sensation of irritation projected in consciousness to the pruritic zone, which area is supplied by the first four sacral segments of the spinal cord. If then we admit, as we must in view of the invalidity of the psychic theory, that it is the conscious appreciation of an irritation we must find the source of such stimulation and consequent irritation. Needless to say, the territory which we must survey extends over the entire nervous system.

Knowing that according to Müller's law of the specific energy of the senses, that no kind of sensation can be produced by external causes which cannot be equally excited in the absence of external causes by intrinsic changes in the nerves, we must look with critical eye not only upon the perceptual apparatus of the nervous system, by means of which changes in the external world are translated from stimuli into appropriate nerve impulses, but we must also scan the conducting apparatus as being capable under certain conditions of giving rise to like impressions. Thus pruritus, being a sensation, may actually be perceived in consciousness by appropriate changes within the nerve channels without regard to stimuli received at the perceptual end organs and this is actually noticed in those cases without evident local pathology. Within the sense of the above quoted law the sensation may arise from stimulation at any susceptible focus in the nervous pathway from the periphery to the cerebral cortex.

Where are these points of susceptibility to stimulation and consequent irritation? The presence of the myelin sheath around the conducting nerve fibres precludes the probabilities of stimulation along these pathways and narrows the probabilities to three points, namely, the peripheral end organs or amyelinated fibres immediately proximal thereto, the synaptic junctions or proximities in the posterior spinal ganglion or the lateral horn of the spinal cord or, lastly, in the cortical cells of the brain.

CLASSIFICATION.

The discussion thus far has brought me to a point where, admitting that a real sensation is evoked, I must needs classify the causes which evoke it. I am quite conscious of the fact that the usual classification of such causes is into constitutional, reflex and local —but since it is my object to make this a complete analysis the analytical process must be pursued until a fundamental basis is struck from which a theory can be formulated.

The most fundamental and the most useful classification which presents itself to my mind is that of: 1. Direct pruritus, and, 2, indirect pruritus.

Under the heading of direct pruritus we can, with good logic, place all those various causes which affect their stimulation by direct action upon the peripheral nerve endings in the pruritic zone. The action may be on or in the skin of this zone and still be a direct pruritus.

The group of causes which I am including under the generic term of indirect pruritus includes all those causes which have hitherto been called constitutional or reflex. To both these terms I have strong objection on the ground that they are neither descriptive nor accurate. Hence, as misleading appellations they should be abolished.

To substantiate this suggestion and to refute any possible counter argument on the part of those who are well satisfied with those terms I will immediately submit my own views on direct and indirect pruritus. At a little later point I will explain on the basis of my own theory the relation these conditions have to pruritus ani and anal pruritus.

To set forth in greater detail exactly what I mean by the term direct pruritus I would state that in all those cases in which traumatism of the peripheral nerve endings occurs by virtue of abrasion, avulsion, compression, physical or chemical maceration of the epidermis and its therein contained peripheral end organs and the amyelinated nerve fibres immediately proximal thereto, direct pruritus occurs. In other words, such processes are, in my opinion, sufficient to cause the generation of afferent stimuli of greater intensity than those causing normal tactile sensations and that these abnormally intense afferent stimuli are perceived in consciousness as irritation.

The peripheral location of the causative agent in direct pruritus can be demonstrated by the complete removal of the pruritus by the infiltration of the epidermis in this region with local anesthetics or by operative procedure such as sacral nerve blocking or superficial neurotomy.

As to indirect pruritus innumerable clinical observations and the bulk of medical literature will support the statements that I am about to make. I quote no authorities, for the reason that these observations have been made and reported by so many investigators that it is needless.

---

*Read before the Twenty-third Annual Meeting of the American Proctologic Society, St. Louis, Mo., May 22 and 23, 1922.

In many of those chronic diseases of the stomach associated with dyspepsia, which will be termed chronic gastritis, there is added to the clinical picture the condition known as pruritus of the anus. This is particularly true in cases associated with much gastric fermentation. In these cases a cure or relief of the gastric condition often brings about a parallel relief in the pruritus. Medical literature reports the association in some cases of carcinoma of the stomach with pruritus and many other chronic diseases of the gastrointestinal tract such as chronic colitis, chronic constipation, fecal retention, and so forth, have also been observed to have an apparent relation with the causation of pruritus ani or anal pruritus.

In a closely similar manner an identical apparent relation has been seen to exist in some cases with chronic diseases of the genitourinary tract. As examples of this chronic endometritis, chronic prostatitis, hypertrophied prostate and chronic urethritis may be mentioned.

Of the other chronic visceral diseases which at times appear to bear a relation to this condition, obstructive derangements of the liver such as hypertrophic cirrhosis of the liver are notable instances. Chronic cholecystitis, chronic nephritis, cystic calculus and neoplastic growths of the liver have each contributed their share of examples of this relation to pruritus ani and anal pruritus. Other instances might be furnished, but these are sufficient at present for our purpose.

HYPOTHESIS.

Bearing in mind the observations above mentioned, it will be noted that the general factors involved are that chronic visceral diseases are very frequently associated with pruritus ani and anal pruritus. These chronic visceral diseases are those that are associated in most cases with chronic inflammation and in almost all cases with a departure in size from the normal either by virtue of hypertrophy, hyperplasia, congestion or distention. Knowing that each of these viscera is supplied with a network of nerve fibres which are particularly abundant in the capsule, it is logical to assume that a departure from the normal size of such organ would cause the generation of afferent nervous stimuli. Those diseases which Osler states as having pruritus as a concurrent condition are diabetes, Hodgkin's disease, lymphoid leucemia, and exophthalmic goitre. All of these diseases, it will be noted, involve a departure in size of the viscera they affect.

It is my firm belief that whenever a viscus is the seat of chronic inflammation, congestion, hyperplasia, hypertrophy, distention or dilatation a stream of afferent stimuli are generated by the mechanical tension on the neural arborizations terminating in its capsule and such stimuli are transmitted by the afferent visceral nerves to the central nervous system.

The viscera, however, are supplied by fibres of the autonomic nervous system and these fibres are not able to convey pain. Langley, Dogiel, and Ranson have, however, proved that the afferent nerves from these viscera come into synaptic relation with the somatic afferents in the ganglia of the posterior nerve root and also in the lateral horn of the spinal cord.

It seems plausible, therefore, to assume that these abnormal afferent impulses from the viscera lead to the stimulation of somatic afferents by creating an irritable focus in the posterior spinal ganglion and that the function of sensation being more commonly utilized in reference to the somatic afferents the irritant stimulus is referred in consciousness, not to its true source but to the place from which such stimuli are habitually received and hence the irritation is referred to the skin of the area supplied by the particular somatic afferent nerve affected. This is a transference of sensation which is exactly analogous in principle with the misreference of pain but that it is not a reflex must be evident from an examination of the anatomical facts.

Now in applying this hypothesis to the particular instance of pruritus ani and anal pruritus attention is drawn to the following facts of anatomical structure: The pruritic zone is supplied by sensory nerves which have their origin in the first four sacral segments. These same segments are in intimate neural connection with not only the pelvic viscera but also with the other abdominal viscera. It will be remembered that the third along with the second or fourth sacral nerve in addition to receiving gray rami communicantes with the sacral autonomics sends a large white ramus communicans or visceral branch direct to the pelvic plexus and viscera. The intimate connections between the various plexuses, the hypogastric plexus and the aortic plexuses bring the superior and inferior mesenteric plexuses into close relation with these sacral segments.

The afferent nerves from the viscera have long been assumed, first by Dogiel and later by others to end their travel centripetally by coming into synaptic relation with the cells of the posterior spinal ganglion by means of the white ramus communications or, by means of the same channel, they may pass through the posterior spinal ganglion and end in the lateral horn of the spinal cord in synaptic relation with the commissural cells of the intermediolateral tract at that level or some higher or lower level. The sympathetic neurons in contradistinction to those of the central nervous system have been shown to come into multiple relations with the various segments. It is thus readily seen that this transference of sensation may come in segments apparently removed from the source of afferent visceral stimuli.

Clinical observation of the frequent association of visceral disease can thus be linked in a logical manner with this manifestation of transference of afferent stimuli and their consequent misreference of localization. This phenomenon is evidenced clinically as pruritus of the anus of the indirect type.

The fact that it is an indirect pruritus is clearly demonstrable by its continued existence after the tissue of the pruritic zone has been thoroughly infiltrated with local anesthetic, after sacral nerve blocking or after superficial neurotomy.

In answer to the question which probably presents itself to your mind as to why such a transference of sensation is not evidenced as pain it must be recalled that pain, like other sensations, has a definite threshold. If we assume that the irritative stimulus which produces the transferred impulse causing the sensation of pruritus is below that threshold and hence incapable of producing the sensation of pain we can readily conceive how it is appreciated in consciousness as an irritation to which we have given the name of itching or pruritus. As a matter of clinical fact these cases of pruritus will frequently tell you that at some times the pruritus becomes so intense that it actually does pain them and in such cases I assume that the threshold of pain has been crossed.

TO RECAPITULATE.

I believe that all cases of pruritus of the anus can be clinically divided into two classes: The one a direct pruritus of the anus, due to the direct irritation of the peripheral nerve endings in the pruritic zone and in which cases the source of irritation actually causes a primary pathology and whose direct nature can be demonstrated by the abolition of pruritic sensation by local anesthetization or superficial neurotomy.

The other an indirect pruritus of the anus, due to the perception of the pruritic sensation which in consciousness is referred to the pruritic zone, an area which is at the inception of the pruritus devoid of any pathological condition at all. This phenomenon is due to the transference of an irritable stimulus from the visceral afferent nerves to a normal somatic afferent nerve channel or pathway and the consequent misreference or error in localization of the sensation.

This indirect pruritus although devoid of any local pathological condition at its inception induces a desire to scratch which results in the pathological changes previously noted, namely, first, a traumatic, chronic dermatitis and in many cases secondly an infective chronic dermatitis. These secondary pathological changes in the tissues of the pruritic zone lead to an added component of direct pruritus of the anus. As a matter of clinical fact sooner or later in all these cases of indirect pruritus of the anus there is superimposed the element of direct pruritus of anus.

Indirect pruritus of the anus may be demonstrated to be an indirect pruritus by the lack of abolition of the pruritus by local anesthetization, nerve blocking or neurotomy and by the discovery of a source of visceral abnormal afferent stimuli. Owing to the addition in most cases of an element of direct pruritus there may be effected, by the methods above mentioned, an apparent decrease in the intensity of the pruritus or by virtue of counterirritation a temporary total relief. The indirect component of the pruritus, however, returns quite soon and from then on is constant in its intensity.

CLASSIFICATIONS OTHER THAN THE FOREGOING.

That this phenomenon of indirect pruritus is not a reflex condition must be selfevident in view of the foregoing so will not be further mentioned. It is a misnomer and should be omitted in describing indirect pruritus.

In regard to the socalled constitutional causes of pruritus of the anus one has but to consider the pathology of those diseases to which it is commonly ascribed to see that the associated pruritus comes under the classification of either indirect or direct pruritus.

Consider, for example, that diseases to which it is commonly attributed, namely, diabetes mellitus. Its mode of action in these cases is presumed to be due to the irritant action of the diabetic urine upon the skin of the pruritic zone. That this is not the case was proven by the experiments of Veit which I have duplicated for my own satisfaction. They consist in the application of pads saturated with solutions in normal urine of glucose of a strength varying from one tenth per cent. to four tenths per cent. over the perianal region for a period of two to three weeks. No pruritus of the anus develops. If the condition be due to the excess of blood sugar throughout the body circulation one would expect a generalized pruritus and not a distinctly localized affair such as this condition is. When we consider, however, that in these cases of diabetes mellitus the liver is usually considerably enlarged; that dilatation of the stomach is common; that a diffuse nephritis is often present and that the constant lesion of the disease is a chronic interstitial pancreatitis (with degeneration of the islands of Langerhans in some cases), when we consider all of the preceding pathological data—we can readily conceive the generation of enough afferent, abnormal stimuli to cause indirect pruritus. It is also noteworthy that peripheral neuritis when occurring in diabetes usually affects the third sacral nerve.

Similar in manner to the ease with which the pruritus of the anus associated with diabetes mellitus can be definitely classified as an indirect pruritus of the anus, so, too, can the remainder of causes hitherto classified as constitutional be assigned to either one or the other of the types that I have previously suggested, namely, direct or indirect pruritus. To explain in detail how jaundice, gout and rheumatism or other constitutional diseases which have been mentioned in past literature as being causes of pruritus ani fit into the classification I have made would require more time than can be allotted at this moment, so it must perforce be reserved for some future discussion.

Of the various theories of etiology the same may be said but, in passing, I will say that the general indictment of being secondary and not primary in significance may with good logic be brought against the majority of such theories, as, for example, that it is due to a fibrosis of the nerve endings, that it is due to the deposition of an inflammatory exudate in the skin or that it is due to a definite dermal infection.

DISEASE OR SYMPTOM?

Coming now to the inevitable question: Is this condition a symptom or a disease? From time immemorial opinion has been divided as to whether this condition is a disease or merely the symptom of a disease.

This is quite natural inasmuch as we have had no standardized and generally accepted conception as to its exact nature. Nor is general medical opinion definitely formed as to what constitutes a disease and what constitutes a predominant symptom of a disease, the term disease often being figuratively and inaccurately applied.

With this discrepancy on the one hand in the conception of the nature of the matter in question and on the other hand the lack of a fairly defined standard by which to measure it, it is not surprising that opinions should be so diverse. Thus, those who believed in one theory of pathogenesis were inclined to mitigate its importance and pronounce it a symptom while those adhering to another view elevated it to the plane of a distinct clinical entity.

A consensus of definitions given by dictionaries and encyclopedias now in vogue with the medical profession gives us the following: The word disease is the speech equivalent for a departure, general or local, from the normal structural or functional status of a vital organism. The word symptom represents a circumstance coincident with a disease whose nature, character and location it serves to indicate.

In regard to the question that still remains: Is this condition a disease per se or is it a symptom among others?

Measuring the condition as we know it by the standards set forth in the above definitions we come to the following conclusions:

That the direct form of pruritus of the anus is in itself a clinical entity cannot be denied. The fissure caused by the passage of a hard, constipated stool or the maceration of epidermis by the acrid secretion of fistulæ may be a definite etiological factor in the resulting disease, but the process from then on is a distinct clinical entity with its own pathology and symptoms. That such conditions as constipation or fistulæ contribute, by furnishing the inciting agent, in no way invalidates the statement that the condition is per se a distinct entity any more than the fact that autointoxication is instrumental in the production of arteriosclerosis makes this condition a component of the former instead of an individual clinical entity.

In regard, however, to the other form of pruritus of the anus which I have referred to previously as indirect pruritus we are confronted with the fact that there is no primary local pathological condition, that the pathological condition found is of a secondary nature and that the pruritus exists before the pathological condition develops. It is, then, merely a subjective manifestation of another clinical entity and merely attains and maintains its prominence as a symptom because of the fact that the primary cause is not removed. However, as has been noted, these cases of indirect pruritus sooner or later have added to them the component of direct pruritus and under these circumstances we have direct pruritus, the disease, concomitant with indirect pruritus, the symptom.

NOMENCLATURE.

As a suggestion, recognizing the value of using terms with which we are familiar and which have acquired the weight of long usage, I would suggest that we term direct pruritus as pruritus ani and that we reserve the term anal pruritus for the form known as indirect pruritus.

Thus an adaptation of existing terms is accomplished which, without coining any new terms, has the advantage of specifying the clinical nature of the condition in question.

Fracture of the Head and Neck of the Radius

By JACOB GROSSMAN, M.D.,
New York
Chief of the Orthopedic Clinic, Lebanon Hospital.

Fracture of the head and neck of the radius occurs more commonly than was formerly believed. The head and neck are prone to fracture on account of their exposed subcutaneous position. They are readily palpable and can be felt rotating at the radiohumeral joint. The fracture is usually the result of a direct injury and occasionally may result from an indirect injury, such for instance as where a patient while falling attempts to save himself from injury by stretching out his hand. When the patient falls, striking the outer side of the elbow, the head of the radius is compressed between the ground and the coronoid process at the lesser sigmoid cavity, with the result that a portion of the head is cracked off. Occasionally a stellate fracture may result. The external epicondyle of the humerus may also be the site of a chipping fracture. When the fracture results from indirect violence the head of the radius is jammed against the capitellum.

The chief sign of this type of fracture is a so-called wincing tenderness, elicited by direct pressure upon the head or neck of the radius. Pain may also be produced by pronating and supinating the forearm. There may be swelling in the region of the radiohumeral joint, due to effusion from a traumatic synovitis. The swelling may also be due in part to hemorrhage into the joint. Ecchymosis may appear late and is generally found below the radiohumeral joint. In one of our cases there was extensive ecchymosis which encircled the affected elbow and extended as far up as the middle of the arm.

Fracture of the head or neck of the radius may be accompanied by luxation of the elbow, fracture of the external epicondyle and occasionally by injuries of the wrist.

An interesting condition, especially in children, which should be remembered when making a differential diagnosis of the various elbow injuries is that known as traumatic palsy of the forearm. It is one in which a partial dislocation of the head of the radius results from a trauma to the upper extremity. The history of the nature of the trauma and the subsequent picture are characteristic. The patient had been dragged by the wrists or raised by the wrists, following which there is disability and pain when manipulation of the affected extremity is attempted. The limb hangs limply at the side as if it were a flaccid paralysis. Hence its name. Slight swelling at the elbow may be present. Ecchymosis, false mobility and deformity are lacking. Passive flexion and extension of the elbow are free and painless. Pronation and supination of the forearm are limited and painful. Upon extreme supination a clicking sound is heard, at which time the head of the radius slips back into its normal position. Immediately thereafter there is resumption of the normal function of the limb. This condition is by no means uncommon and should always be remembered when diagnosis of elbow injuries is made.

ETIOLOGY.

In a series of 150 fractures of the elbow we have met with sixteen in which there was either a fracture of the head or neck of the radius or both. This is about ten and a half per cent. of the series. Of the sixteen, ten or about two thirds were in females and six in males. The youngest patient was two years of age and the oldest was fifty-two. Seven of the patients gave a history of a fall and striking upon the outstretched palm. The height of the fall varied from a distance in one instance of two steps and in another of fifteen steps. Others slipped and fell on the pavement. One child fell from a high chair. The other nine had sustained the fracture as a result of direct violence, that is an injury in which the outer aspect of the elbow was the recipient of the blow.

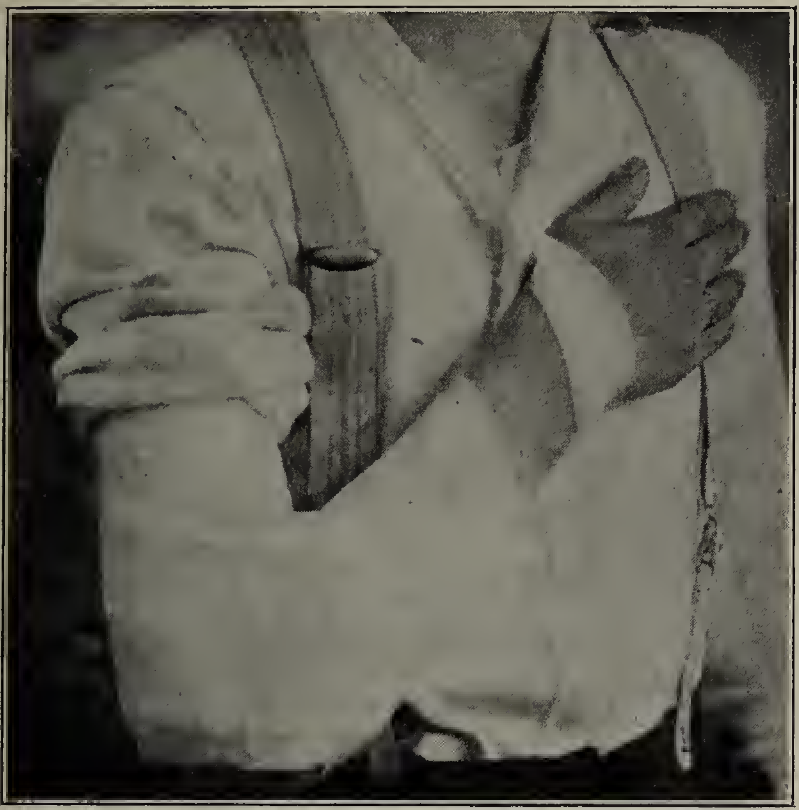

Fig. 1.—Author's method of retaining the forearm in acute flexion.

VARIETIES OF FRACTURE.

Most of the fractures were of the head of the radius. The head was cracked in one portion with occasionally displacement of the fragment. In one instance there was a stellate fracture. Some showed fracture of the neck and these fortunately were impacted. In a few instances both the head and neck were the site of fracture. None of the cases showed marked displacement of the fragments. Hence operative interference was unnecessary.

SYMPTOMATOLOGY.

Subjective.—The chief complaints in every instance were pain and disability.

Objective.—The commonest objective symptoms were swelling, ecchymosis, and tenderness. The swelling was usually localized in the outer side of the elbow in the region of the radiohumeral joint. Ecchymosis varied in extent. In some instances it was very trivial. In one instance it encircled the entire elbow and extended to the middle of the arm. It usually appeared about thirty-six hours after injury. The tenderness was excruciating and of the wincing type. It was elicited by direct pressure and also by supinating and pronating the forearm. It was usually localized to the region of the radiohumeral joint.

TREATMENT.

The treatment of fracture of the head and neck of the radius is the same as that used in the treatment of intraarticular fractures in general. One must remember that the head of the radius lies wholly within the joint, is covered with synovial membrane and is bathed with synovial fluid. Hence fracture is usually accompanied by traumatic synovitis and some hemorrhage within the joint. In view of these facts the best treatment is immobilization with early baking. Movements should be delayed until the swelling in the radiohumeral joint has subsided. In selecting an immobilizing agent, one must remember that the head of the radius enters into the formation of two joints, the radiohumeral and the radioulnar and the fixation agent must control both these joints. A very simple and efficient fixation agent is one which maintains the elbow in acute flexion. The bare forearm is fully flexed so that the hand rests on the opposite shoulder and the elbow is carried well forward on the chest. The position is fixed by a strip of adhesive plaster encircling the arm and forearm just above the elbow joint. The forearm is now bandaged to the arm by figure of eight turns of a flannel bandage. Before applying this dressing the arm should be dried and powdered and boric acid cotton placed in the elbow crease and axilla to absorb the perspiration and keep the parts dry. The limb is retained in position by a sling around the neck.

Immobilization should be continued until the swelling in the radiohumeral joint disappears. Baking should be begun immediately and continued daily throughout the treatment. Passive movements followed shortly by active movements should be begun as soon as the fluid in the joint disappears.

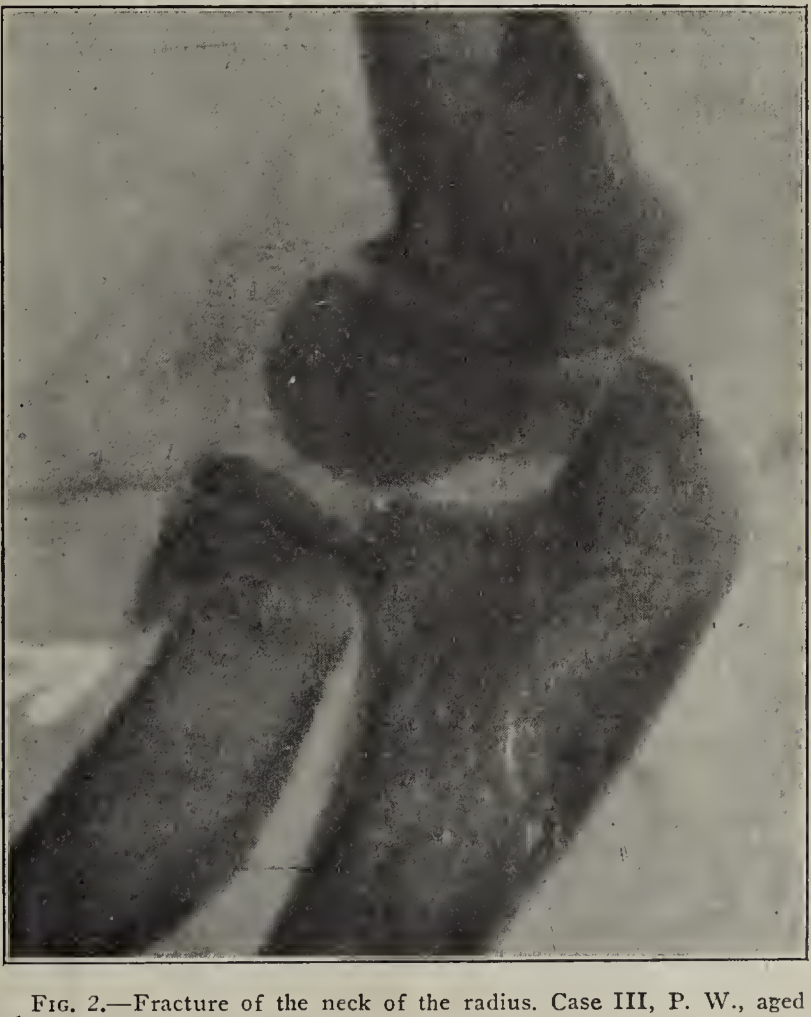

Fig. 2.—Fracture of the neck of the radius. Case III, P. W., aged eleven.

Where a fragment has been separated and displaced, so as to block flexion of the forearm and it cannot be reduced by conservative measures, operative interference may become necessary whereby the offending fragment is either replaced in its proper position or removed.

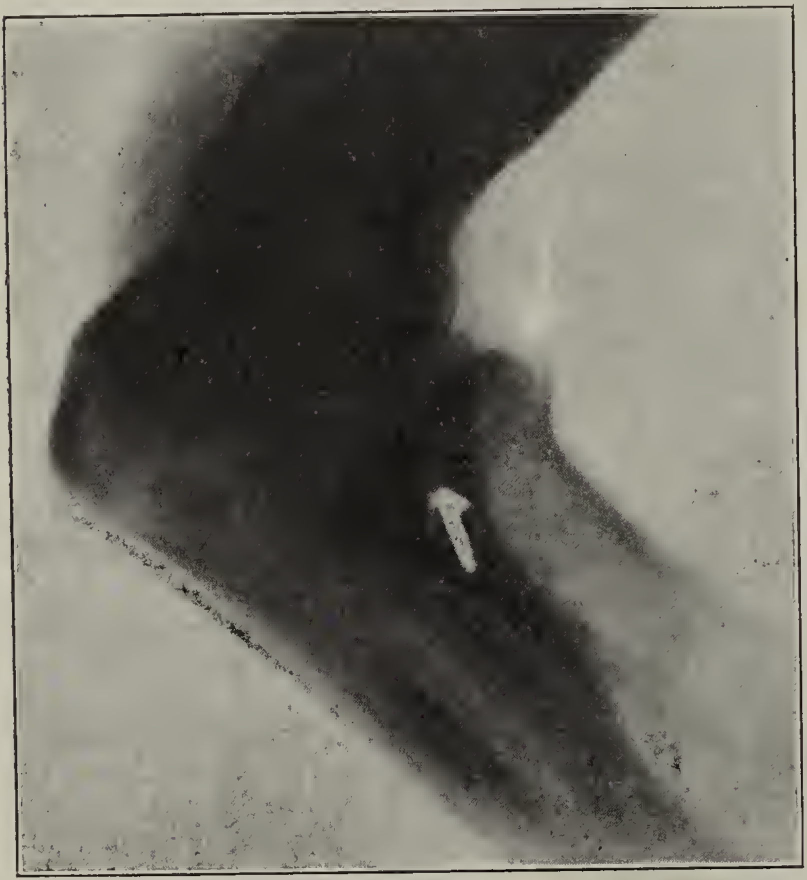

FIG. 3.—Fracture of head of radius. Case IV, J. M., aged twenty-four years.

PROGNOSIS.

The prognosis is good in all cases except where the fragment is too small to be replaced and in old cases where proper reduction and immobilization were not performed.

CASE REPORTS.

CASE I.—Pearl D. slipped and fell downstairs a distance of four steps, striking the outer side of her right elbow. There was pain referred to the affected elbow and disability. There was slight swelling localized in the region of the radiohumeral joint. Ecchymosis was absent. There was no deformity. The relationship of the three processes (external, internal condyles of the humerus and the olecranon process of the ulna) was not disturbed. There was excruciating tenderness over the upper part of the radius in the region of the neck. Flexion and extension of the elbow were almost normal, pronation and supination of the forearm were very painful and restricted. A diagnosis of fracture of the neck of the radius was made and proper treatment instituted. Subsequent x ray confirmed the diagnosis. The patient made an uneventful recovery, being discharged four weeks after the initial visit to the clinic.

CASE II.—Anna K., twenty-four years of age. One week before her visit to our clinic the patient tripped and fell down stairs, a distance of fifteen steps. She landed on her outstretched hand. There was pain referred to the right elbow and lower part of the arm. Complete disability was also present. There was marked swelling localized in the entire elbow and lower part of the arm. Ecchymosis was extensive and encircled the elbow and covered the lower part of the arm. Extension, flexion, rotation of the forearm were very painful and markedly restricted. There was excruciating tenderness over the upper part of the radius, in the region of the radiohumeral joint. A diagnosis of fracture of the head of the radius was made and proper treatment instituted. Subsequent x ray picture confirmed the diagnosis. The patient made an uneventful recovery five weeks after her first visit to the clinic.

CASE III.—Phillip W., eleven years of age, slipped and fell, striking on his outstretched hand. The chief complaints were pain in the right elbow and disability. There was swelling localized to the outer side of the right elbow in the region of the radiohumeral joint. Ecchymosis was present and localized to the outer side of the elbow. The relationship of the external condyle, internal condyle and the olecranon process was not disturbed. There was excruciating tenderness over the upper part of the radius in the region of the neck. Flexion and extension of the elbow were slightly restricted. Pronation and supination of the forearm were painful and markedly restricted. A diagnosis of fracture of the neck of the radius was made and proper treatment instituted. Subsequent x ray picture confirmed the diagnosis.

The patient made an uneventual recovery, being discharged four weeks after the accident.

CASE IV.—John Mc. E., twenty-four years of age. A few days before his visit to our clinic the patient fell and struck on his outstretched hand. Shortly thereafter he experienced severe pain in his elbow. There was also disability. There was swelling localized to the outer side of the elbow in the region of the radiohumeral joint. Ecchymosis which was trivial was localized in same region. The relationship of the external condyle, internal condyle and olecranon process was not disturbed. There was excruciating tenderness localized in the upper part of the radius in the region of the head. Flexion and ex-

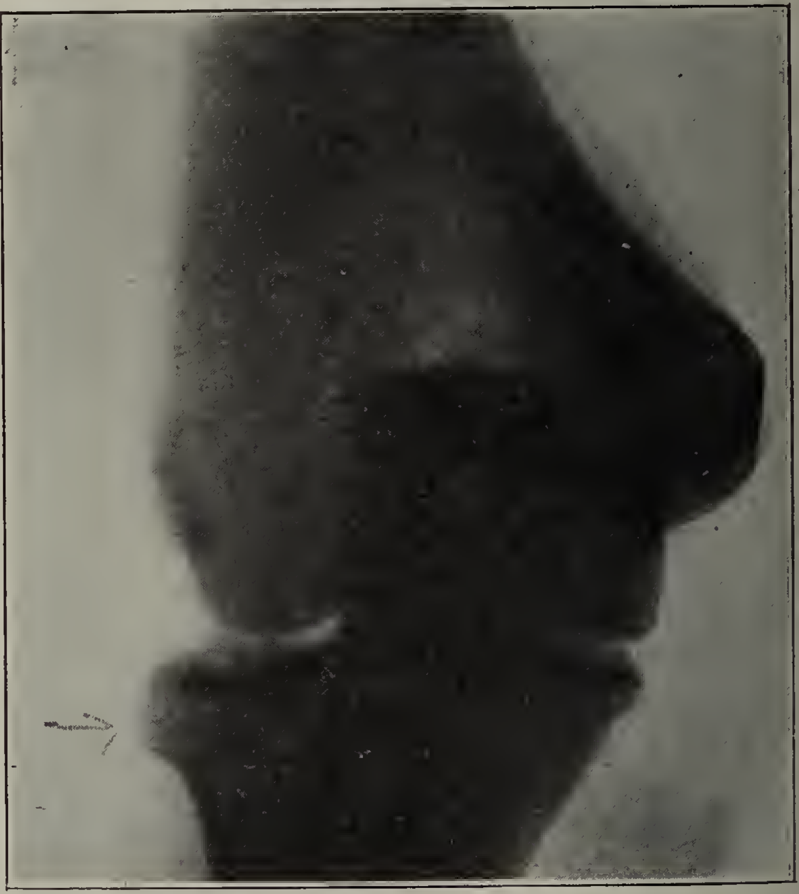

FIG. 4.—Another view of Case IV.

tension of the elbow were slightly restricted, pronation and supination of the forearm were markedly restricted and very painful. A diagnosis of fracture of the head of the radius was made and proper treatment instituted. Subsequent x ray picture confirmed the diagnosis. The patient made an uneventful recovery, being discharged five weeks after the onset of the injury.

The histories and physical findings of the remaining cases are practically identical to those just enumerated, hence the report in detail will be omitted.

SUMMARY AND CONCLUSIONS.

1. Fracture of the head and neck of the radius is not an uncommon condition. Sixteen cases having been present in a series of 150 cases of elbow fractures.

2. It may result from a fairly mild trauma, either direct or indirect.

3. The best position and method of treatment is that of acute flexion.

4. Baking should be instituted from the first. Motion, either active or passive, should be delayed until the fluid has disappeared from the radiohumeral joint.

5. In arriving at a diagnosis one should always eliminate the presence of socalled traumatic palsy.

6. The prognosis is good in all cases except in those in which the fragments are so small and displacement so marked that they cannot be replaced. In these cases operative interference must be resorted to.

The Indications for the Transfusion of Blood*

By I. S. RAVDIN, M.D.,
Philadelphia.

The history of transfusion in the middle of the last century is being repeated at the present time. From 1863 to 1884 transfusion was supposed to be a cureall and the assertions made for it were preposterous. Cohnheim, in 1883, in reviewing the literature on transfusion up to that time, stated that it was inexcusable to use any blood for intravenous injection in which clotting had already taken place, or blood of another species. But until Von Bergemann in 1884, published his important work, transfusion was still a subject of great interest. He came to the conclusion that the only permissible transfusion was the direct one from artery to vein. That the failures were far greater than the successes can be seen in the action of the French government, which forbade the procedure until the Faculty of Paris should give its approval. Such death blows to a process already on the wane because of the frequency of its disastrous results, together with the fact that the use of saline solutions for intravenous injection was becoming more general, caused the transfusion of blood to be abandoned as a therapeutic measure.

In 1898, Crile, of Cleveland, began a series of experiments which marked the introduction of transfusion as a safe and valuable therapeutic procedure. He began by using arteriovenous suture, which came into existence through the work of Payr and Murphy. He later adopted the ring cannula method, first suggested by Nitze in 1897 and carried out by Payr in 1900. The technic of vascular anastomosis became so perfected through the work of Carrel, of the Rockefeller Institute, that this method, in the hands of men experienced in bloodvessel surgery, came into vogue. Crile's cannula method, as well as Carrel's method, presented so many technical difficulties for the average surgeon that other methods were sought for. Then in rapid succession followed the paraffined glass cylinder method first advocated by Kimpton and Brown in 1913 and later by Vincent and Percy, with their modifications. After this, in 1913, came the syringe cannula method of Lindeman. Ziemssen had used this method twenty years before, but it never became popular until revived and perfected by Lindeman. In 1916, came the simultaneous work of Lewisohn and Weil in this country, of D'Agote in Buenos Aires and of Jeanbrau of Montpelier on the use of sodium citrate as an anticoagulant.

Heretofore hirudin, ammonia and the oxalates had been advised and widely used as anticoagulants, but each in turn had been discarded. The work of these four men reopened the entire subject of transfusion. At about this same time (1916) Satterlee and Hooker also described their pipette cannula method.

Since then the modifications have been too numerous to mention. Brenziger, Martin and Lee, and Unger have described apparatus which can be used successfully by surgeons trained in their use. The chief fact to come out of all the recent work, however, is that nearly all the blood from donors can be obtained by the needle, using one of the many described, and that in at least a large percentage of cases the blood can be given by the needle, thus avoiding the destruction of a useful vein.

Very recently the choice of method has been the source of considerable argument. Surgeons who have used the citrate method successfully are perhaps too inclined, because of its simplicity, to regard it as the method of choice in all cases. On the other hand advocates of the unmodified method especially those who are using apparatus of their own design have been only too eager to condemn the citrate method.

In the majority of cases the successful administration of the blood, not the method, is of prime importance. The extreme opposition to every other method by a surgeon advocating his own apparatus makes one wary of the reliability of the judgment of many of the recent writers. When one considers that an institution like the Mayo Clinic with an experience running up in the thousands routinely uses the citrate method, we know that its antagonists must exaggerate its dangers. There are undoubtedly cases such as the severe anemias in which less reaction follows the administration of blood by one of the unmodified methods, however as a general rule it is safe to leave the choice of the method to the surgeon with experience in transfusion.

---

*Read before the Northern Medical Association of Philadelphia.

Since frequently the transfusion is done by the intern or house surgeon whose experience and skill is limited the preferable methods are the citrate method of Lewisohn and the unmodified method of Kimpton and Brown. While it is true that the Lindeman and Unger methods may have some advantages such as the rapid transference of small quantities when unmodified blood is used they are frequently unsuccessful when used by the tyro.

INDICATIONS.

It is a mistake to consider transfusion as a cureall or as a last resort in hopeless cases. The physician who is not carried away by an enthusiasm similar to that of the period from 1836 to 1884 will be better able to define clearly the useful indications for transfusion.

We have found the indications divisible into three groups, and increased experience in the procedure will give the clinician definite ideas of the types of cases which will benefit by it.

Loss of blood.—To this group belong all those cases of anemia from acute hemorrhage as well as those cases due to small, long continued blood losses. Some of the latter, however, finally fall into the second group.

Diseased blood.—Transfusion for this group serves the following functions: 1. To stimulate hematopoietic function. 2. To increase coagulability. 3. To add to the oxygen carrying capacity. 4. To increase the bactericidal or autotoxic properties of the blood. 5. To increase the general nutrition.

Blood transfusion is invaluable in all cases of hemorrhage after injury or operation. In this group belong the hemorrhages of childbirth, ectopic gestation, miscarriages, fibroids, and other uterine hemorrhages. Acute bleeding from injuries, from gastric, duodenal or intestinal ulcers, and from ruptured viscera belongs here also. In the case of acute massive hemorrhage the surgeon sees the most miraculous results following transfusion. One of our patients admitted cold, pulseless and unconscious after a crushing injury to the thigh was revived by transfusion of 2100 c.c. of citrated blood. These patients can be operated on much more safely and the convalescence is much more rapid with a transfusion than without. The average amount of blood which we use for transfusion in acute hemorrhage is 750 to 1000 c. c.

The question of when to transfuse for acute hemorrhage depends upon the surgeon, but we are sure that if all borderline cases were transfused before the socalled limit of bleeding was reached the mortality from acute hemorrhage would be less. This will not only make up for the blood loss but it will also undoubtedly help to check the hemorrhage, provided the amount of blood given is not too large or given in too short a time.

In repeated small hemorrhages the anemia may become so marked that the blood picture will simulate that of a primary anemia. Transfusion before the hemorrhage is controlled, and after this until the blood picture again assumes a somewhat normal appearance, act nearly as specifically as in the first group. In cases of chronic bleeding the coagulation mechanism becomes deranged and the longer the bleeding continues the less likely it is to stop spontaneously, although the coagulation time of the blood outside of the body is but little delayed.

In these cases we transfuse repeatedly once or even twice a week, until the blood picture shows that the blood forming organs are again functioning normally. In this way an apparently poor surgical risk may be turned into a good one.

Diseases of the blood.—Here the new blood acts as a therapeutic agent. First, through hematopoietic function. In this subsection belong the primary anemias and extreme secondary anemias. The transfusion is done with the hope that it will stimulate hematopoietic function. This probably occurs through the products of blood disintegration which stimulate the bone marrow. The fate of the transfused blood as recently determined by Ashby must also be considered. She sums up her conclusions by saying "The life of the transfused corpuscle is long; it has been found to extend for thirty days or more. The beneficial results of transfusion are without doubt not due primarily to a stimulating effect on the bone marrow, but, it is reasonable to assume, to the functioning of the transfused corpuscles." Several transfusions are necessary and it is often noted that the second transfusion is of much more benefit than the first. In this type of case we welcome a moderate reaction, since these patients seem to get the best ultimate results. For this reason some writers advise small doses of incompatible food.

Primary pernicious anemia.—Vogel and McCurdy in 1913 first carefully studied the effect of blood transfusion and regeneration in primary pernicious anemia. In our cases we find that, while transfusion is of no permanent value, by repeated transfusions we have prolonged a patient's life for as long as four years. This patient has had sixteen transfusions, in this period, and is still able to go about. We feel that transfusion offers more for pernicious anemia than any other form of treatment and that all patients except those in extremis will benefit by repeated transfusions. The remission which is brought about comes sooner and lasts longer, as a rule, than one occurring under medical treatment alone, and the life of the patient may be saved for some years.

If a remission is not brought about it is well to change donors. In this way results can be obtained by transfusion which make it superior to any other therapeutic measure. The important thing to remember is that under no circumstances should the patient be allowed to become so weak that transfusion is a dangerous procedure, but when the red cells continue to decrease and the hemoglobin reaches 30 it is time to begin transfusions and to continue them at short intervals until the blood picture shows decided improvement.

Aplastic anemia.—Here there is no tendency to blood regeneration, the leucoblastic and erythroblastic activity both being demoralized. Although blood transfusion does not even cause a remission in these cases, rapidly repeated transfusions (twice a week) will so increase the number of blood cells and hemoglobin, and relieve the symptoms that the patient can be comfortable for a variable period, though never a long one.

Splenic anemia.—In this group we include splenic anemia and Banti's disease. Transfusion plus splenectomy offers the best opportunity for obtaining a cure. If the blood count is low after operation the transfusion may be repeated in order to give the blood forming organs an impetus to resume their normal function.

Leucemia.—I have transfused in only one case of leucemia. The patient, who was suffering from acute lymphatic leucemia, was transfused four times within ten days, with a total of 2200 c.c. of blood. When he was admitted his blood count was red blood cells, 905,000; white blood cells, 31,400; hemoglobin, 25 per cent. On discharge his count was, red blood cells, 3,600,000; white blood cells, 45,000; hemoglobin, 33 per cent. However this improvement was only shortlived and an acute exodus followed soon after discharge. This is often the case following transfusion in leucemia and the most we can hope to do is to attempt to tide the patient over until the disease takes on a more chronic form and other treatment can be begun.

Hemolytic icteroanemia.—In this condition transfusion does not offer permanent relief but is of value in improving the anemia enough to warrant the operation of splenectomy, which is a curative measure. Transfusion following the operation shortens convalescence and hastens the return of a normal blood picture.

In the last patient I had, a nurse, transfusion was resorted to five times before splenectomy. At operation a large spleen was removed, a gallbladder full of stones, and a dermoid cyst of the ovary. She was again transfused on the table. The recovery was uneventful.

To increase coagulability.—To this group belong the cases of, a, melena neonatorum; b, hemophilia; c, jaundice; d, purpura; e, secondary hemorrhagic diseases complicating such conditions as grave anemias, leucemias, and severe infections. It is in these hemorrhagic diatheses that we find the results of blood transfusion uniformly good. Melena neonatorum and hemophilia usually yield as if by magic to a single transfusion, although transfusion does not confer immunity to hemophiliacs against further hemorrhage. I have found citrated blood just as efficacious in these cases as unmodified blood. This has been definitely proved by Pemberton. If the first transfusion has not the desired effect, then a second one should be done with a different donor. Temporizing with less effective measures, as horse serum and various coagulants, may cost a life.

In a case of cholemia following cholecystectomy in which the patient had a number of fairly large hemorrhages the patient's condition became very serious and blood transfusion was decided upon. There was immediate improvement in the patient's general condition and there were no further hemorrhages although the patient was transfused thereafter for the secondary anemia.

To increase the oxygen carrying capacity of the blood.—Here belong the cases of illuminating gas poisoning. Only a few cases have been reported. Carbon monoxide has a stronger affinity for hemoglobin than oxygen. When carbon monoxide combines with the hemoglobin the red corpuscle is removed from the circulation as effectively as in acute hemorrhage, as far as its oxygen carrying capacity is concerned. The patient should be bled at the time of the transfusion. This may be difficult because the blood often becomes of a syrupy consistency.

To increase the bactericidal and antitoxic properties of the blood.—Transfusion has no place in the acute infections unless the socalled vaccination transfusions suggested by Heyd and Hooker, that is, transfusion with immunized blood, open new possibilities. There is, however, a large group of cases suffering from subacute and chronic infections which is materially benefitted by transfusion. These patients as a rule, are profoundly anemic, and transfusion should not be delayed until the body has lost its power of reaction. The transfusion is a stimulant to the hematopoietic organs, throws into the circulation functionating corpuscles and at the same time probably contains antibodies which may affect the life of the organism causing the infection, or so stimulate the patient's forces as to help them to develop an active immunity. Cases of chronic suppurating wounds do more than justify the procedure. We have used it in chronic suppurative disease of the hip joint and in malignant endocarditis. While the results in the latter were not especially favorable those in the former have been exceptionally good.

For its antitoxic effect transfusion is of use in the toxemia of pregnancy with doubtful results, and in sprue, purpura and pellagra. While the beneficial effect is undoubted in purpura, in the other conditions the results are as yet doubtful. Lindeman reported four cases of tropical sprue treated by transfusion, with apparent recovery in every case. In the toxemia of pneumonia transfusion has been used with questionable results. Our only patient, in extremity when transfused, died.

As a stimulant in the various cachexias.—Here the transfusion is used for its general nutritive effect. It improves the vitality of the tissue cells. It frequently will permit radical operative procedure which before transfusion would have been out of the question. In debilitating conditions such as inoperable carcinoma it will improve the patient's general condition and prolong life, but its use in cases of this type is one of the causes for the procedure again falling into disrepute. A field open to its use is the malnutritions of childhood, especially marasmus, and cachexia from prolonged diarrheas.

Shock.—The value of transfusion in shock, especially if associated with hemorrhage, has received so much attention recently that it is needless to discuss it further here. It is just as useful in civilian as in military practice. In the cases of shock without hemorrhage, in which there is apparently no change in the blood volume, we must not expect as brilliant results as in those associated with hemorrhage. If an operation is necessary the patient who has been transfused is better able to stand the shock due to additional trauma.

An ingenious means of meeting this indication in patients who are to undergo long operative procedures has recently been devised by Dr. Grant of the University Hospital. Plethoric patients who were being prepared for cranial operations were bled twenty-four to thirty-six hours before operation and the citrated blood which had kept on ice was reintroduced when the first evidences of shock appeared.

CONCLUSIONS.

1. Transfusion is a specific in acute hemorrhage where the socalled limit of bleeding has not been reached, in melena and in the hemorrhage of hemophilia.
2. It is of definite value in primary pernicious anemia in hastening and prolonging remissions. It is indicated in cases of severe secondary anemia—after transfusion operations on debilitated or anemic individuals may often be safely undertaken that otherwise would involve a serious risk.
3. Transfusion in shock is not as efficacious as in cases of shock with hemorrhage.
4. We have not been able to prove the value of transfusion in acute infections, but in chronic infections we have had results justifying its use.
5. It is of improved value in acute leucemia. In aplastic anemia it is a palliative measure.
6. In the severe anemias the use of unmodified blood by one of a number of methods is probably to be preferred but in all other conditions the citrate method will give equally good results.

An Improved Method for Diagnosis and Localization of Duodenal and Gastric Ulcers*

By S. L. CASH, M.D.,
New York.

A large number of peptic ulcers escape discovery. Hemorrhage, large or small, from the lesion continues an important factor in diagnosis, and may be found in about the same number of active cases in which the x ray is effective. X ray findings or blood from the lesion may each be the deciding feature in a given case.

As a comparison of the prevalence of blood in ulcer with x ray findings, a classical illustration representing maximum results is the table of Baetjer and Friedenwald (1).

Total 743, x ray positive 84.4 per cent., blood about 60 per cent. with 516 examined.

Cases proved by operation 185, x ray positive 79.4 per cent., blood 84 per cent., 108 in 128 examined.

Undoubted cases not proved by operation 323, x ray positive 84 per cent., blood 81 per cent., 205 in 255 examined.

Doubtful cases 235, x ray positive 89.7 per cent., blood 81 per cent., 108 in 133 examined.

These figures, while high, prove ulcer a frequent cause of gastric and duodenal hemorrhage, that is, blood in slight or profuse quantity, and it is necessary in applying the stool test to consider sources other than ulcer of blood in the digestive tract. About ninety-five per cent. of duodenal ulcers are situated within an inch and a half of the pylorus; ten to seventeen per cent. are on the pyloric ring. Of gastric ulcers four fifths are on or near the lesser curvature and posterior wall.

Another feature is, as Moynihan expresses it, "a remarkable and sustained contraction of the circular muscular fibres of the stomach that occur in or near the segment on which the ulcer is situated." These are factors in the use of the string test; with blood at the lesion even where it is slight they make the test practical.

Einhorn's string test is an ingenious instrument, but has objections, all due to its small size. To remove these objections I have used a test made from a loosely knitted tubular silk braid. It is white, flexible, compressible and half an inch in diameter. The test consists of two parts; the upper, extending from the teeth, is a silk string, preferably No. 15 twisted silk. The lower part of the test is a section of the braid.

For the lower part of the stomach and the duodenum the average length of the braid is ten to fourteen inches, the attached string ten to sixteen inches. For the lower part of the esophagus and the upper part of the stomach the anchor string is shortened; in gastroptosis cases and the lower part of the duodenum greater lengths of the parts are required. Repeated tests show the length of the string or braid necessary. Measurements from the teeth to the pylorus vary from a fixed standard in different subjects and to locate this part by arbitrary measurements is subject to error.

No cup is needed since the braid offers obvious evidence in three ways of its passage through the pylorus. The braid is easily swallowed. A practical method is to fold the braid into a compact mass, moisten it with water, milk or ice cream, and use water or milk if necessary to wash it down; or it may be enclosed in a cachet. It is swallowed at bedtime, the patient being careful to take no food or drink with the slightest coloring, for a number of hours previous to swallowing.

Appreciation by the physician of the motor function of the stomach will govern this time. The braid must remain in place at least three hours or, if no discomfort ensues, which is rare, until morning.

Hot water sipped slowly facilitates passage of the pylorus. On removal of the braid, which the patient may do, it should not be touched, but suspended free from contact until dry. Under these conditions it will retain the shape acquired while in place. Or if a microscopical or chemical examination is required, the physician should remove it.

---

*Read at the Bellevue Hospital Alumni Society, November 1, 1922.

As a routine at least three tests are given. One for the pylorus and duodenum, then one for the stomach, and the third according to findings of these, in conjunction with the history, physical examination, etc. If the patient is a good subject two braids may be used in the stomach at the same time; one is sufficient in the duodenum.

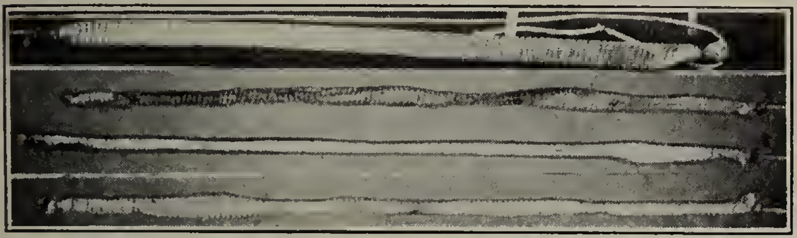

Fig. 1.—1. Braid test before use. 2. Chronic gastric ulcer two inches in diameter near pyloric orifice; blood stains from edges of ulcer; between these braid not constricted; prevented by induration, pyloric constriction below second spot, no bile stain; verified by operation: also beginning carcinoma. Entire braid colored dirty brown from blood and seropurulent mixture; blood, pus, epithelium. 3. Hour glass stomach, gastric ulcer lesser border. Small stain upper part. Second test, five months, similar in detail, stain, constrictions, etc. 4. Syphilis of stomach; in first or second part of duodenum, constriction at lower part; bile stain to lower blood stain.

The features of the braid are: 1. A large surface for contact, with large stains for gross, chemical, and microscopic examination. 2. Size and compressibility permit contact with irregular surfaces. 3. Size and texture prevent cutting of the tissues. 4. Compression of the braid by the pylorus localizes this part and thereby the lesion, whether duodenal, gastric or pyloric. 5. Passage through is also shown by bile stain, in conjunction with the pyloric and other markings on the braid. Bile regurgitation is indicated by the approximation of the bile stain to the pyloric marking and by the degree of bile coloring, and as evidence of duodenal obstruction is valuable when bile is not vomited nor obtained from the stomach. A spastic pylorus prevents bile regurgitation into the stomach in the majority of instances of duodenal obstruction. Localization of the pylorus by the braid is an aid in determining the length of the tube needed in nonsurgical draining of the gallbladder, in duodenal lavage, and in treatment of ulcer with the duodenal tube. 6. It is useful in testing the progress of healing and for posttreatment observation. 7. It eliminates the cup and bulb which in aggravated ulceration at least are objectionable. The cup may be used with the braid. 8. When the x ray reveals the lesion the braid determines whether it is acute or chronic. Where the x ray is not obtainable or is inefficient the braid test may be useful. 9. The braid proportioned for the stomach has free play in contrast to the string test that extends into the duodenum with a bead or cup attached.

Any acute or unhealed ulcer will give off blood, and by repeated application of the tests a stain should be obtained. A degree of judgment and persistence in applying the test is a requisite. It has proved the prevalence of remittancy in ulcers, particularly duodenal. Similarity of constrictions, or lack of them, and twists and strains in several tests from the same subject are interesting and this shaping and staining is permanently retained. The mucus hardens and fixes it after drying. Other uses for the braid are suggested, as in treatment, and as a test for acid in the stomach when the tube cannot be used.

Case I.—In this patient the symptoms began six years previously, with constipation, and during the past three years he had suffered from the sensation of fullness after meals, with much belching half an hour after meals, and lasting one to three hours. This was relieved by milk of magnesia. He also suffered from occasional headaches, and had a poor appetite the past two months.

The first braid test for the lower stomach and the duodenum was negative for blood, with a faint bile stain from lower end to pylorus. The second test showed heavy bile stain reaching to the pylorus.

The third test, that extended to the first part of the duodenum, gave a heavy blood stain with marking fourteen inches from the teeth and no bile. The fourth test of same length showed a shorter but deep blood stain at the same distance with no bile. Later while under treatment in bed, two other braid tests were given and showed bile stain on the duodenal part reaching to the pylorus.

These verified the previous diagnosis of duodenal obstruction, evidenced by duodenal succession on repeated examination. Operation showed an unusual duodenal dilatation with mesenteric obstruction; there was a slight thickening of the pyloric ring but no other evidence of ulcer. This case illustrates the importance of repeated tests with the braid.

Case II.—The symptoms were indefinite. There was a palpable tumor in the epigastrium, small, hard and smooth with slight pain on pressure. A braid obtained a stain at the outlet of the stomach, and showed spastic contraction of the stomach and pylorus. The Wassermann test was two plus, and the x ray showed an irregular thickening of the first part of the duodenum. Specific medication was given and two months later a second x ray photograph showed that the tumor had almost disappeared. A braid test at the time gave no stain.

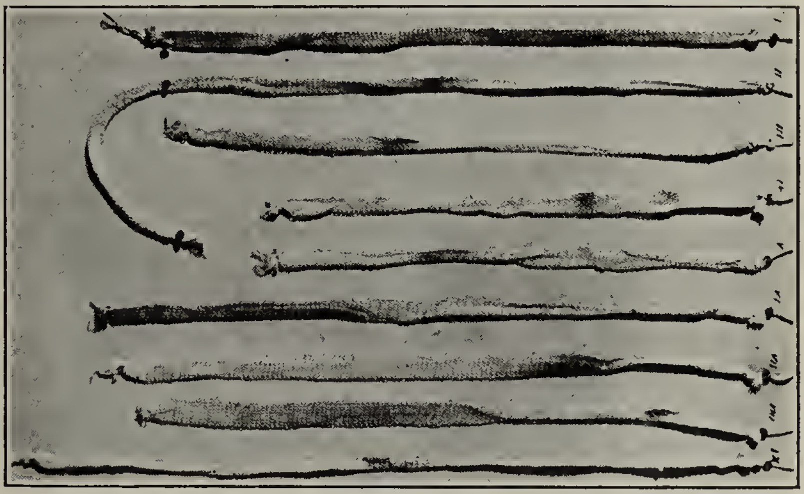

Fig. 2.—1. Duodenal obstruction, bile stain heavy to pylorus, verified by x ray and operation. 2. Pyloric ulcer, no bile stain on four tests, no duodenal obstruction, verified by operation. 3. Duodenal ulcer first part, note pyloric constriction above blood stain, blood stain to lower end. 4. Duodenal ulcer first part, a large one or two smaller shown by two blood spots; pyloric constriction above, constriction by duodenum below. 5. Pyloric ulcer, verified by x ray. 6. Duodenal ulcer, duodenal obstruction; near pylorus, on each side of small dark blood stain fainter blood stain shows with evidence of friction (hyperperistalsis), bile stain to blood spot; verified by x ray and operation. 7. Duodenal ulcer, duodenal obstruction; pyloric constriction above stain, bile stain, moderate (does not show on plate) to blood spot. 8. Jejunal ulcer following gastroenterostomy six tests positive. 9. Ulcer of duodenum, first part, no bile stain, marked contraction (spasm) of stomach, pylorus and duodenum.

A New Frontal Sinus Instrument

By J. A. HAGEMANN, M.D.,
Pittsburgh, Pa.,
Otorhinologist to the Pittsburgh Hospital.

The equanimity enjoyed when using an implement virtually insuring immunity from mishap prompts this presentment of a gouge for use incidental to the operation of draining the frontal sinus. If a Hajek chisel four mm. wide could be bent to an arcuation of 35°, beginning three and a half cm. from the point, with the concave gutter on the convex side of the curve, one would in effect have the instrument devised by me.

The many methods that have been contrived to attain a cure for acute or chronic frontal sinusitis bear witness to the unsettled condition of the problem. Since 1882, when Kocher reported his results in empyema and hydrops of the frontal sinus by entirely removing the anterior wall, a host of modifications have been suggested and practiced. The repellant deformity left after the obliteration of the sinus prompted many to seek an intranasal route that would establish permanent drainage. If human skulls were uniform one might with some assurance shape one's course in accord with the several authors' suggestions. But unfortunately the frontoethmoidal areas vary in brachycephalous and dolichocephalic heads with their sundry modifications, and one must ever feel apprehensive that, in groping, the cerebral compartment may be ingressed. Furthermore, even after one has successfully passed a guiding sound into the sinus by the nasal route, the subsequent laborious abrading with rasps is rather an unsatisfactory procedure. It is conceded that the majority of cases in which an exigent submucous resection of the nasal septum with resection of the anterior third of an obstructive middle turbinate, and exenteration of the anterior ethmoid cells has been done, they will get well under palliative measures. For such as do not respond to this treatment a more radical procedure becomes imperative.

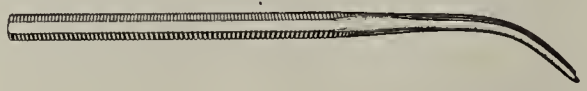

Fig. 1.—Frontal sinus instrument devised by author.

PREOPERATIVE PROCEDURE.

I proceed in the following manner. On the day preceding that of operation, the emergence of the supraorbital nerve from its foramen is indicated by drawing a perpendicular line through the eyebrow with a thin, moistened crystal of nitrate of silver at that point. This becomes a black stroke, serving as a caveat so that one may not inadvertently divide the nerve which would entail protracted, if not permanent, anesthesia of the frontoparietal region. The operation is done under ether anesthesia. The eyebrow is not shaved.

Preceding the administration of the anesthetic, a pledget of gauze saturated with solution adrenalin chloride one to one thousand, is packed into the upper, anterior portion of the nasal cavity of the affected side. This pledget is not removed until the external feature of the operation has been completed. When anesthesia has been attained, plugs of gauze are placed in both posterior nares in the customary way and secured by having strings of the commercial umbilical tape tied about each plug, brought out through the nares and tied taut together behind the head. A mouth gag is inserted and kept in position throughout the operation. With such precaution one is enabled to observe if any blood be accidentally transuding through the postnasal sponges and the anesthetist can more readily perform his functions without discommoding the operator.

TECHNIC OF OPERATION.

After the customary preparatory toilet of the operative field, an incision, penetrating the periosteum, is made, beginning in the midst of the eyebrow just mesial from the dark silver line, and, following the middle of the eyebrow, extending elliptically downward and inward for about three and a half cm. toward the nasal bone. The periosteum is quickly elevated and the spurting vessels stopped by torsion. While an assistant holds the edges of the wound apart by means of small retractors, an opening is made into the sinus with a small gouge and mallet. This aperture is sufficiently enlarged with a ronguer to permit inspection of the interior of the sinus. Pus, granulation tissue or polyps are removed with a spoon curette. Then a section of the anterior wall four mm. wide is removed by cutting upward, parallel with the perpendicular line of the body, with an angular rongeur, as far as the extent of the sinus will permit.

A slender probe is now passed downward through the ostium frontale into the nose and left in this position. The adrenalin soaked pledget of gauze is removed from the nose. The vertical gap made in the frontal wall permits the introduction of my gouge in such manner that its point will hug the under side of the nasal bone when being driven downward with the mallet. This obviates the contingency of a possible encroachment upon dangerous ground.

If the channel communicating with the nose thus fashioned be deemed inadequate, it may be enlarged by use of a rasp. No packing is left in the sinus or nose. The exterior wound is closed with three skin sutures. A dry, sterile pad of gauze is securely bandaged over the wound and respective eye. The postnasal plugs are removed. Before the patient leaves the operating room the intranasal wounded surface is liberally swabbed with a saturated solution of coagulin to obviate the bleeding that sometimes occurs when the ischemia from the adrenalin is waning. There is usually union by primary adhesion leaving a scarcely perceptible scar and the patient may leave the hospital about the tenth day after the operation.

Highland Building.

Bacterial Vaccine Immunization Under Bacterial Intoxication

By G. H. SHERMAN, M.D.,
Detroit, Mich.

No question in medical practice is of more importance than a concrete concept of the influence bacterial vaccines have when given in cases of extensive bacterial intoxication due to acute infection. Much animal experimental work has been done to determine the source of bacterial intoxication but nothing definite has been ascertained by this method concerning the source of the bacterial poison produced by germs like the streptococcus, pneumococcus, staphylococcus, and colon bacillus or the socalled endotoxic organisms. It has been assumed that all the toxic symptoms from infections by endotoxic organisms are due to the setting free of endotoxins as a result of a disintegration of the organisms during the course of the infection. That these germs possess toxic substances in and of themselves, even after they are killed, that will produce toxic symptoms when injected into healthy animals goes without saying, but that does not prove that the intoxication in an active infection is mainly, in part or at all, due to endotoxins derived from disintegrated or destroyed organisms during the process of the infection. Teale (1), by carefully conducted animal experiments, shows that bacterial intoxication is not due to preformed specific endotoxins. Vaughan's contention that bacterial intoxication is due to a splitting up of a bacterial protein and thus setting free the poisonous portion by proteolytic ferment action has never been proven.

The proteose poisoning theory of bacterial intoxication due to absorption of the antitrypsin in the plasma by the infecting bacteria has never been conclusively demonstrated clinically or experimentally. So it appears that some of the oldest concepts along the line of bacterial intoxication are not being sustained.

That bacterial intoxication is not due to a setting free of endotoxins as a result of germ disintegration during the course of an infection may be demonstrated by induced immunization in acute streptococcic infections. Take a case of streptococcus lymphangitis or cellulitis showing rapid extension of the infection with a temperature of 102° or 103° during the first few days with everything indicating a steady progress of the infection for example. Here we have every evidence of the presence of a large number of infecting organisms rapidly increasing in number. By giving a suitable dose of vaccine subcutaneously, and repeating at twelve to twenty-four hour intervals, it is a common experience in such cases to find a material drop in temperature to normal or near normal within twenty-four to thirty-six hours with clinical indications of a retrogression of the infection. This clinical picture shows a positive decrease in germ growth and activity evidently due to a rapid destruction of the infecting organism. If toxic symptoms were due to the liberation of endotoxin from destroyed germs we should have a rise of temperature with increased toxic symptoms after the vaccine injection. But we find the reverse to be true—no rise of temperature but a steady fall. It was the results obtained in this class of cases that induced Wright (2) to say: "Most dramatic and convincing are the successes obtained in streptococcal lymphatitis and streptococcal cellulitis."

Let us take an impending lobar pneumonia during the first six hours after the initial chill with lung congestion progressing toward consolidation, the patient coughing up blood streaked mucus with severe pain in the chest and the temperature about 102.5° for example. In this condition the patient is certainly harboring a large number of pneumococci, the organisms being in the blood as well as in the lungs. By giving such a patient, in this early stage, a subcutaneous injection of a polyvalent pneumococcus, streptococcus, combined vaccine containing 100,000,000 of each organism, and repeated at twelve to twenty-four hour intervals, a normal temperature with an arrest of the infection will be obtained in a vast majority of cases within twenty-four to thirty-six hours with a speedy recovery if the vaccine treatment is continued. Here again we have clinical evidence of rapid germ destruction without toxic symptom development, showing that during the immunizing process with rapid germ destruction, no bacterial intoxication develops from the setting free of the endotoxins contained in the destroyed germs. Wynn (3), a prominent authority of Birmingham, England, was so impressed with the favorable results from the early use of bacterial vaccines in the treatment of pneumonia that he said: "So striking have been the results when vaccines are injected early that I would urge the adoption of this practice." In another article (4) he gives a detailed report of 107 cases of pneumonia which he treated and claims that the use of a suitable vaccine—he employed a mixed polyvalent vaccine—given in the early stages of pneumonia, gives just as striking results as the antitoxin treatment of diphtheria.

I have seen a localized bacterial intoxication develop within four hours from a streptococcus infection produced by a needle prick in the thumb. Within nineteen hours this developed to a streptococcus lymphangitis extending to the shoulder with a temperature of 102.5° and gangrene development at the site of the needle prick. Here the wound was entirely too small to inoculate a large number of germs. Toxic symptoms, however, began to develop soon with every evidence of rapid germ multiplication. It is impossible to ascribe this rapidly progressing bacterial intoxication to endotoxin derived from decomposed killed streptococci or to the poisonous radical of the protein contained in killed streptococci, because this would imply that the streptococci are being rapidly destroyed whereas the entire clinical picture shows rapid bacterial growth. A cultural condition that induces rapid germ destruction never at the same time is conducive to rapid germ multiplication. The endotoxin and split protein theories most certainly do not account for conditions found in such an infection.

It is now generally admitted that germs secrete ferments which they employ to digest the food on which they live. Since this ferment has a destructive influence on the tissues it encounters, it of necessity is toxic. Regarding this germ produced ferment as the real primary cause of bacterial intoxication explains all the phenomena present. The streptococci which were inoculated with the needle found the environment suitable for rapid multiplication. The ferment they secreted rapidly digested the food on which they lived, making rapid growth possible and accounts for the development of toxic symptoms soon after the germs entered the tissues of the thumb. Leucocytes made their appearance but found the condition too toxic to arrest the process. The streptococci continued to grow and multiply with a proportionate increase in toxic ferment secretion to a point of actual tissue destruction with gangrene formation.

The localized toxic effect of the infecting organisms, by means of the ferment they secrete to digest the food on which they live, being recognized and how these involved tissues eventually manage to destroy the invading organisms if recovery takes place, involves the problem of immunization. We know that during the process of overcoming an infection, substances are found as a result of the presence of the infecting organisms that have a destructive influence on these very germs. These substances are commonly known as antibodies and may be regarded as tissue cell produced protective ferments.

The question arises: Are these protective ferments produced by the infected tissues or are they produced by special organs set aside for the purpose of producing immunizing substances? Some pathologists and immunologists believe that antibodies are formed by the internal lymphatic organs. It may be true that in extensive acute infections, the internal lymphatic organs eventually come to the rescue by producing antibodies as a result of the influence brought to bear on them by the toxic materials that have permeated the entire system; but at best this process is a slow one resulting in a prolonged illness and often is too tardy to prevent a fatal termination. The other contention is that all living tissues are endowed with the power of self preservation against bacterial invasion and that these antibodies are produced by the involved tissues themselves as a result of the presence of the infecting organisms. It is readily explained why this is also a prolonged process with frequent fatal terminations. The toxic ferments secreted by the infecting organisms have of necessity a destructive devitalizing influence on the body cells with which they come in contact and instead of stimulating these cells in their defensive capacity to produce protective ferments or antibodies, they are overwhelmed and at least temporarily crippled in their defensive capacity, resulting in a tardy development of antibody with a prolonged illness and a possible fatal termination.

Let us consider these two contentions as elucidated by clinical observations of acute streptococcus or pneumococcus infections under the influence of bacterial vaccine inoculations. If the internal lymphatic organs are the source of antibody formation, this would apply to antibodies produced from vaccine injections as well as from localized infections. That acute streptococcus or pneumococcus infections will show marked clinical symptoms of abatement within one or two days after suitable doses of vaccine have been given, at twelve to twenty-four hour intervals, is a fact which is readily demonstrated, and this can only be accounted for on the ground that rapid antibody formation takes place as a result of the vaccine inoculations. The amount of killed streptococci or killed pneumococci, or both if a mixed vaccine is given, is so small—about 0.0004 of a gram—that the amount of toxin it contains would be infinitesimal as compared to the toxic materials already present in the blood and tissues of the patient; in fact, is so small that it produces no appreciable influence in increased temperature or pulse rate, and consequently could not be expected to have any stimulating influence on the internal lymphatic organs, but definite changes for the better do soon take place.

Wright's contention that the antibody is produced by the tissues into which the vaccine is injected readily accounts for the results obtained. The tissues into which the vaccine is injected are not aware that the injected organisms have been killed. They are intruders that possess the biochemical construction of infecting bacteria minus the power to secrete toxic ferments or of multiplication and must be disposed of. Being killed, they can offer no resistance to their destruction by the body cells with which they come in contact and during the process of destroying these killed germs, protective ferments or antibodies are produced for the destruction of live germs corresponding to those contained in the vaccine. To guard against future infections when body cells are once influenced to produce antibodies they continue to do so as a natural provision for some time thereafter. These excessive antibodies are then conveyed by the circulating medium to the infected area and there aid the involved tissues in overcoming the infection.

This offers a rational explanation of what actually happens in acute infections under bacterial vaccine treatment. This action of vaccines also offers a rational basis for giving vaccines in extensive acute infections. As long as a doctor harbors the thought that the toxic portion of a bacterial vaccine must stimulate the lymphatic internal organs he can see no logical basis for giving vaccines in acute toxic infections. He at once visualizes such a patient as having as large a load as he can safely carry and regards the giving of a vaccine as increasing that load. But, if he grasps the viewpoint, as demonstrated by clinical observations, that the tissues into which the vaccines are injected are thereby aroused to the production of antibodies or protective ferments which neutralize the germ produced ferments or toxins and cripple the infecting organisms in their digestive capacity so phagocytes can attack and destroy them, the advantages of giving bacterial vaccines in acute toxic infections become apparent at once. Germs during the process of invasion digest their way into the tissues they involve by means of the ferment they secrete from their surface and with which they surround themselves. By means of this ferment pneumococci and streptococci often digest their way through the epithelial lining of capillary bloodvessels and gain entrance to the circulating blood where they grow and multiply. Wright (2) classifies these organisms because they are capable of growing in the circulating blood as serophytes and shows that they are destroyed by phagocytic action. A serophyte succeeds in maintaining itself against phagocytic action by means of the digestive ferment with which it digests the food on which it lives. This, in fact, is the only means of defense the germ has.

It is this digestive ferment with which the germ surrounds itself that constitutes the essential element of toxicity in an infection. If the germ succeeds in maintaining an efficient ferment for its digestive activities, phagocytes will not make an attack because instead of digesting the germ, the germ would destroy and digest the phagocyte. What in all probability happens when vaccines are injected under the skin in these acute toxic infections is this:

As a result of the presence of the killed germs at the site of vaccine injection, these tissues become actively engaged to produce antibodies to get rid of the injected killed organisms. More antibodies are produced than are required to dispose of the killed organisms and the excess antibody by means of the circulating medium is conveyed throughout the body. The toxins absorbed from the infected area are thus neutralized which accounts for the rapid relief from toxic symptoms. The antibody also combines with the ferment surrounding the infecting organisms and consequently reduces their toxicity and virulence by crippling their digestive apparatus, making them susceptible to attack by phagocytes and accounts for the rapid retrogression of infection in infected areas.

That this is a correct concept of what takes place is aptly illustrated by the relapses which frequently occur if the vaccine treatment is discontinued too soon after good results have been obtained. In lobar pneumonia, for example, if the vaccines are employed during the first day as a rule the temperature and pulse will come to normal within one or two days. If the vaccine treatment is then discontinued, a relapse with a spread of the pneumonic process frequently occurs within a day or two after the vaccine treatment is discontinued which is not the case if the vaccine treatment is continued until all symptoms of infection have subsided. Furthermore it is found that larger doses are required when treating extensive acute toxic infections than in subacute and chronic conditions and the injections must be made at much shorter intervals at least at daily intervals and in severe cases at twelve hour intervals. The necessity of frequently repeating large doses would indicate the quantitative requirement for antibody formation by repeatedly activating fresh areas of tissue cells. That the tissues into which vaccine is injected produce the antibody is also demonstrated by the clinical observation that not as good results are obtained if the vaccine is repeatedly injected in approximately the same area as when an absolutely new area is selected for each injection. Some doctors even contend that better results are obtained by injecting vaccine in divided doses.

From these considerations it is evident that in bacterial vaccines we have an efficient absolutely safe biological remedy which is nontoxic when applied in the treatment of acute infections and which should be applied at the earliest possible moment in all acute streptococcus, pneumococcus and other pyogenic infections because by the early administration of the vaccine, the best results are obtained.

The Dawn of Surgery

Notes from Homer

By JONATHAN WRIGHT, M.D.,
Pleasantville, N. Y.

There are still primitive men and still a few primitive men in primitive surroundings, but since the time when there were few civilized men there has been a curious decline in the social status of the practitioners of medicine. When they split off from the high priest and the chieftain of the clan, when differentiation, which is only another word for civilization, had advanced thus far they had their first and most serious loss of caste. It certainly did not help matters much, and on the whole neither did it make matters much worse when they split off from philosophy, so far as their social prestige was concerned, but when medicine was again broken up in the course of the growth of cities into minute trades and mechanical arts and connection with philosophy bid fair to be severed altogether, when the medical man had no time for the arts in their higher definition or science in its broader development, then serious degradation really set in for medicine and it is not to be checked in its downward course on the intellectual plane by group practice in our time either. It is not so much group practice the medical man needs as the grouping in his head of various cosmic and metaphysical, psychological facts and feelings in active communication with the materialistic unit whereby he gains his daily bread and an ephemeral reputation.

However, leaving at one side this critical epitome of the differentiations of the pursuits of men in their later manifestations, since the time of early primitive man when we find him in close union with or in a more or less equal rivalry with the heads of the state and the church the first fall from power and influence was the most serious. It is not necessary in this instance to turn to the ethnological notes of modern primitive life any more than to realize that this tendency for law, religion and medicine to dwell beneath the common shield of magic is all but universal among primitive tribes. The chieftains, kings and emperors have lasted until our time, even popes persist, but the medicine man as a potential force had an early fall and came long ago to an absolute loss of temporal power, somewhat resumed in our day by boards of public health. Kings and popes have come to the verge of it, but we still know them as politicians. With the exception of some Latin countries of the new world and our upstart health officers the medical man has no political power by virtue of his profession.

It was not always so even at the origin of our culture. In the *Iliad* of Homer we plainly perceive the affiliation of medicine with supreme power and Æsculapius as the son of Apollo had a high seat among the hierarchy. The physician in Homer is a hero and a comrade of heroes and yet we find on the wall paintings and in the encaustic work of vases and the etchings on less fragile material the physician almost in a menial position. In one of them, if we search out the one to which Daremberg alludes, (1) we see Menelaus represented of heroic size and Machaon small, deferential, looking up at him like a slave, but that is not the way Homer represents them at all. Arktinus, perhaps even a hundred years later than the author of the *Odyssey,* puts the surgeon in the second place and if nothing else, even as early as this, (775-740 B.C.?), we see the beginning of his drift towards the barber shop. "The earth shaking Neptune," Arktinus says in his poem on the ruin of Troy, "bestowed rich gifts on Machaon and Podaleirus, but he made one more honorable than the other. To the first he gave deft hands, shaped to draw the arrow from the flesh, to make incisions and to cure all wounds. He placed in the heart of the second, however, a marvelous sagacity for recognizing hidden disease and for curing desperate cases. It is Podaleirus and he was the first to discover the madness of Ajax by his blazing eyes and the melancholy of his temperament." For Homer it was Machaon that had the stage and the chieftains too dabbled in surgery. We cannot fail to see in this that though wounds and blows were the end of life and their treatment the ends of life for the doctor in Homer we begin to get the intrusion of philosophy in Arktinus and he starts the mechanics of medicine to the rear.

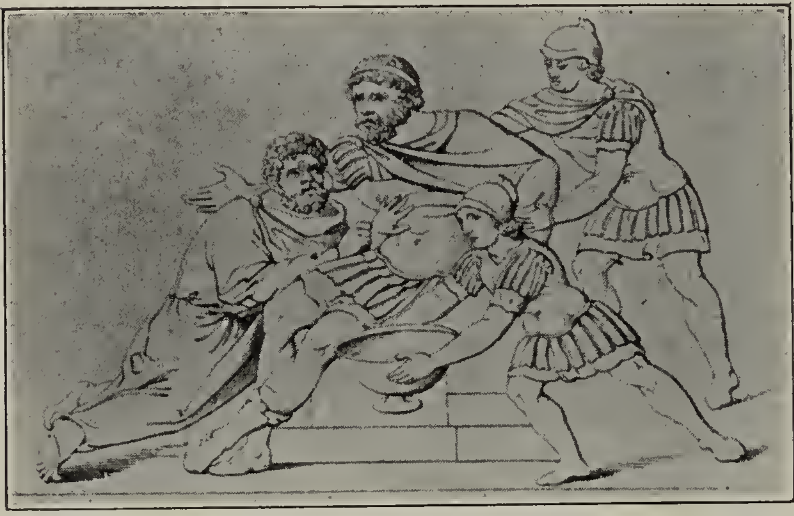

FIG. 1.—Diagnosis and treatment. (From the Greco-Roman period.)

By the time of Plato, though he speaks with respect of Hippocrates, we find him saying (2) the arts of the physician, like those of many other mechanics, are accounted vulgar. There seems less reason to think of their low social standing in the language Daremberg quotes from Plato's great predecessor and ancestor, but from this fragment of Solon's we can scarcely avoid seeing that surgeons were not so high in the world as when they associated with heroes and led their thirty ships filled with warriors to the siege of Troy. Solon speaks of it chiefly as a trade and of its triumphs as chiefly attained by the laying on of hands. Yet it was out of the chieftains of the Achains, skilled in the treatment of wounds, that grew the army surgeons of Xenophon, out of their tents grew the field hospitals that existed in the Roman army and very likely in earlier times still in the expeditionary armies of the Persians and the Greeks. Who the poet Eurypylus was or when and where he lived I do not know, but Athenaeus mentions him and Cicero (3a) quotes from him, referring to the old army: "The wounded fill the porches of the children of Æsculapius," and Eurypylus is speaking of the affairs of the Argives. Xenophon in the Anabasis refers to the army surgeons in a way that allows the inference they were no novelty in his day and he speaks elsewhere of Persian army surgeons, but one gets no mention of them in Herodotus, who says he lived four hundred years after Homer and he was himself older than Xenophon by forty years at least. Herodotus was well acquainted with doctors and has much to say of Democedes and others but nothing of the army doctors. We get little out of the *Odyssey* in the way of surgery. The scar of Ulysses, which betrayed him to his nurse on his return home, we learn resulted from a wound of the leg in his youth made by a wild boar's tusk and it was cured by the sons of Autolycus, who bound it up skilfully and stayed the black blood with a song of healing (XIX-455) which matches Solon's remarks on the laying on of hands. Now this is magic, but it is not the magic we find in the *Iliad.* How shall we mark the difference? Shall we say in the *Iliad* there is a higher grade of magic at work? In the *Iliad* we are still in that stage of the magic healing of wounds by the intervention of a goddess or a demigod, in the *Odyssey* of a fakir, yet we have too little material to base any such distinction upon, but I want to insist again, as I have done elsewhere, that the magic of Homer is our magic, the magic of the northland not of the dusky Mediterraneans. We have to come down to the century of Sophocles, a literal century, for he lived a hundred years and overlapped the birth and youth of Hippocrates, before we find a Greek writer speaking with disrespect of the medicine man's

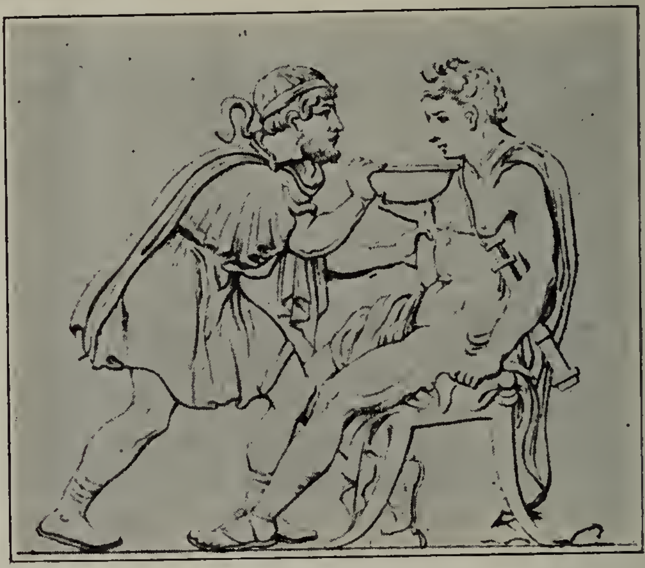

FIG. 2.—Nestor giving wounded Machaon a strengthening potion. (See Friedländer, Vol. I, 373.)

whining a song over a sore that calls for the knife. It must have been a respectable Æsculapius and his cult, even though he had his snake with him, whom Sophocles welcomed to Athens with an ode as high priest of the temple.

In the *Iliad* we find not only the two sons of Æsculapius physicians and warriors, but they were leaders, "the cunning leeches, Podaleirus and Machaon. And with them were arrayed their thirty hollow ships." (4a) It was Machaon to whom Lord Agamemnon called that he should look after Menelaus, captain of the Achaians, whom a Trojan or some Lycian archer had wounded with a bowshot, glorious for him but full of grief for the chief of men, his brother. (4b) It was said that Menelaus was wounded in the groin or thigh and the illustration, (Fig. I) said to date from the Greco-Roman period, may have been inspired by this passage in Homer of Machaon succoring him It is more than hinted in the *Iliad* that Menelaus had his failings and that fortitude was not one of his virtues and we know how his wife tired of him. Whenever this representation was executed, it was a period at least when obsequiousness to the aristocracy did not overcome the rules of art and Machaon has the same or practically the same physical proportions as Menelaus, if this is the scene it is meant to portray and in the sense of representing Homer s ideas of the army leech it is historically correct. From the golden haired Menelaus, wounded through the clasped belt, Machaon, the godlike hero came and drew forth the arrow, whose keen barbs were broken backwards as he did so. "Then he loosened the glistering belt and the kirtle of mail beneath and the steel thigh pieces, that the coppersmith fashioned and when he saw the wound where the bitter arrow had lighted, he sucked out the blood and cunningly spread thereon soothing drugs, such as Cheiron of his goodwill had imparted to his sire." Now it was because the arrow was poisoned it was bitter and because it was poisoned Machaon sucked the wound. The critics have good philological and other good reasons for thus interpreting the epithet applied to the Homeric arrows. "Bitter" was poison because it was herbs chiefly that were so used and these herbs were bitter. Among primitive men other poisons are known, it is true, but in the Babylonian dialects as well as in the Homeric usage the terms were interchangeable or closely associated. Thus Apollo probably used, in the thought of the original Homeric bard, poisoned arrows to spread disease in the Achaian fleet, and we as surgeons can see no reason why the son of Æsculapius sucked the wound, except that which moves the medicine man to do the same thing now in localities where poison for the arrow can be found. So we still treat snake bites in an emergency. The later Greeks were ashamed of this barbarian method of war in the bard they revered, more ashamed than we are of poison gas, and they deleted, it is insisted, such passages in the revised copies of Homer which were made at Athens, in the time of Pisistratus, or of Aristarchus in the time of the first Ptolemies at Alexandria, who, Cicero says, (5) refuses to attribute verse he does not like to Homer, marking with the obelisk and interpolating. Certainly by the time of Aristarchus and possibly as early as Pisistratus, the close affiliation of bitterness with poison, etymologically, had been lost. It has only lately been recovered by the philologists with the help of the archeologists and the ethnologists.

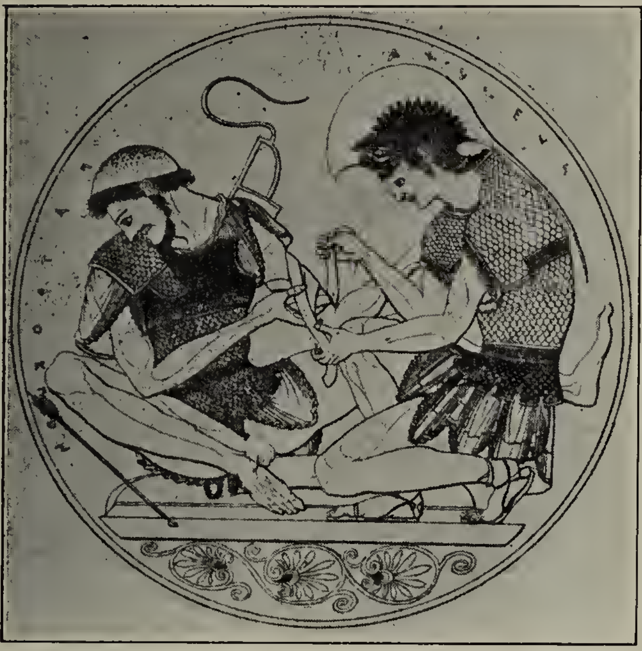

Fig. 3.—Achilles binding the arm of Patroclus. From a painting inside a vase.

Alexandros, Paris, lord of the fair tressed Helen, smote Machaon on the right shoulder with a three barbed arrow, (4c) and then it may be remarked that Nestor, doughty old warrior and true gallant as he was, had a maid servant whom he kept in his tent and Hekamede, the wise woman, who had her medical arts from Egypt, ministered to Machaon, whom Eurypylos had declared in need of a good leech himself. But the mess she mixed for Nestor's wounded guest, would hardly have been attractive even to the driest man in this dry epoch. Pramnian wine may indeed have been good, but why it should have been desecrated with goats' milk cheese, grated in a brazen grater, and barley flour sprinkled over

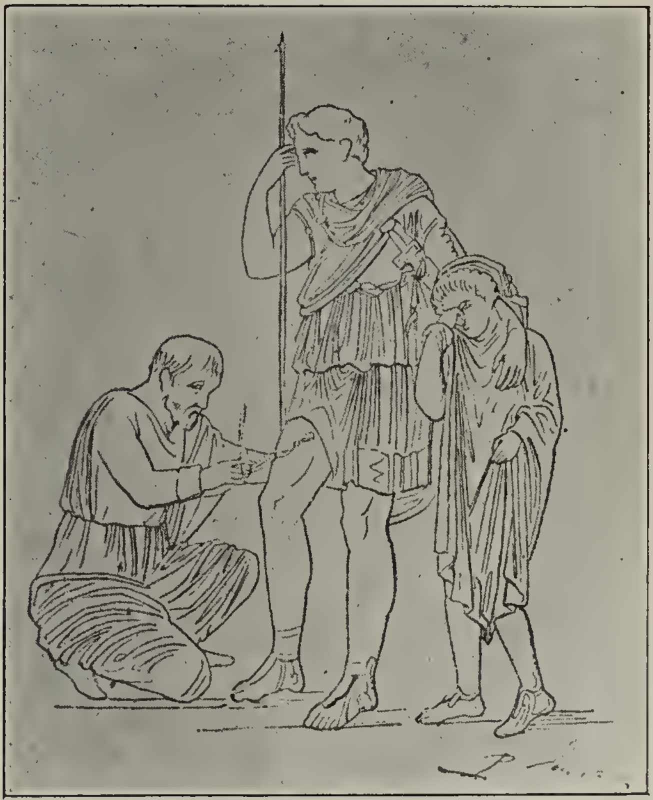

Fig. 4.—Using a forceps on a wound from a painting of Iasis and Æneas at Pompeii.

it, does not appear. Such a milk punch or high ball appeals neither to the modern dietitian nor to the modern inebriate. Though several books of Homer are passed over after Machaon got his wound before we meet with the group in the tent of Nestor the action is much more rapid and the fiery old gentlemen, when the cry of battle rose, could linger no longer, "albeit over his wine," and was off exclaiming to Machaon, "Nay, sit where thou art and drink the bright wine, till Hekamede of the fair tresses shall heat warm water for the bath and wash away the clotted blood." (4d) Wine and woman doubtless wrought a cure, but can we find any more sincere tribute to a noble guest than for Nestor to leave him with both? That, it seems to me, establishes at once the standing of the army surgeon at Troy, and that is the last we hear of Machaon in the *Iliad*.

This is also one of the incidents that fired the imaginations of later Greek artists. The loving cup of Nestor, according to Athenaeus, (5) was to be seen at Capua in his day, probably about as authentic as some of our own antiques, for Homer has told the copyists how to make it. "A right goodly cup the old man brought from home, embossed with studs of gold and four handles there were to it and round each two golden doves were feeding and to the cup were two feet below." We get a hint as to the size of a drink for those old warriors and deep trencher men, cast in the giant mould of demigods and heroes. "Another man could scarcely have lifted the cup, when it was full, but Nestor raised it easily."

It is not Machaon alone by any means who treated wounds, though the Homeric Eurypylus declared a leech worth more than many men. As has been intimated we find other chieftains practising surgery and we find the later Greek artists fully recognizing this in such work as has been preserved for us. Nearly a hundred years ago there was found in an Etruscan tomb at Volsci the socalled cup of Sosias and inside it was adorned, perhaps sometime in the IVth century before Christ, with a representation of Achilles putting a bandage around the arm of Patroclus (Fig. 3). The figure of eight bandage that is going on looks somewhat professional and there can be no doubt that Sosias had Achilles in mind as a medical hero as well as a warrior. He was the pupil of Cheiron and he taught Patroclus what he knew from him about wounds, as Eurypylus said when he came limping out of the battle, (4c) wounded in the thigh with an arrow, the sweat running in streams down from his head and shoulders and from his cruel wound the black blood welling, but he knew what he was talking about when he beseeched Patroclus. "Do thou succor me and lead me back to the black ship and cut the arrow out of my thigh and wash away the black blood from it with warm water and smear soft healing drugs thereover, these good herbs whereof they say thou hast learned from Achilles, whom Cheiron taught, the most righteous of the Centaurs." . . . "Patroclus sat in the hut of the kindly Eurypylus . . . and on his cruel wound was laying herbs to medicine his dark pain," but he like Nestor too was carried away by the rush of war around him, starting up and smiting his two thighs with his hands flatwise. "No longer may I abide with thee here, though great thy need . . . but thee let thy squire comfort while I hasten to Achilles that I may urge him to join the battle. (4e) The heroes fall in heaps and about them the leeches skilled in medicine are busy healing their wounds. (4f)

When Apollo struck Patroclus with his hand and rendered him senseless Euphorbus ran him through with a spear and Hector finished him, but where he got the wound in the arm we see Achilles treating I do not know. The roller bandage betokens a stage of civilization, to say nothing of medicine, which we are not accustomed to associate with Homeric Greeks and one would be surprised that it should have existed in the epoch to which one can conjecturally assign this vase of Sosias did we not know from Hippocrates himself in the Vth Century B. C., how bandaging like this was a fad among practitioners of which he made sport. As for Patroclus having a wound of the arm that may have been of record in a copy of Homer we no longer possess today or it may have been a story of those coming later living on the crumbs from Homer's table, as Æschylus said of himself, or still again it may have been an error of Sosias in the first place with his mind fired by the fad of his day rather than stocked with accurate Homeric lore. All these things may have been so, but more likely the reproduction has been so labelled by some much more recent copyist who also was imperfectly acquainted with Homer's account of the doings of Homeric heroes, but so far as I know, when Patroclus got that buffet on the ear from Apollo and the spear thrust in the back from Euphorbus and the knightly Hector gave him another in the belly as he saw him lying there in the dust we sum up all, and it is enough, we know of the wounds of the bosom friend of Achilles in our modern Homers. He was a much abused man, but that wound in the arm in the illustration is unaccounted for.

How easily errors creep into the interpretations of ancient works of art all the way along the line from the original artists through the archeologist and those to whom he furnishes material multiplied by the thousand on the modern press, copied from the one to the other until it arrives at the hand of the final chronicler, himself a weak and fallible agent in the dissemination of knowledge, socalled, is exemplified in another illustration (Fig. 4) which is fallen from its high estate on the walls at Pompeii into my humble hands, Iasis and Æneas. The latter was one of the few Homeric heroes, as is well known, who did not come to an unhappy and inglorious end. There are few modern readers of Virgil's immortal epic who do not often wish the same ill fate for the man who with imperturbable Roman vanity and arrogance told Dido, *"magna pars fui."* But for mother's help on many occasions he would never have lived to trifle with poor Dido and it is Venus's lovely self again who steps in in the XIIth book of the Æneid to do more than earthly hands could do for her sweet tiresome prig of a son, the ever blooming, radiant Venus born from the foam of the sea, where all life and much love begins. But "Iasis" was a bewilderment rather than a help to me in trying to find just where Æneas again needed his mother. By accident more than searching diligently, I stumbled on the line: (6)

> *Iamque aderat Phoebo ante alios dilectus Iapyx*
> *Iasides. . . . . . .*

It was Iapyx, the son of Iasis, who used the extracting forceps on Æneas, leaning in a very poor posture on his spear, discouraged, while Turnus rages across the field of battle in the distance seeking his foe until by divine help Æneas is healed from his chance arrow wound and the gods produce his enemy for his elaborately prepared *coup de grâce*. It is marvelous how the art of the poet has triumphed in the Æneid with Æneas in it. Here, however, it is for us to take note that the forceps are in use in the time of the very mediocre Pompeian artist and we got no mention of them in our citations from Homer. We may question the archeological knowledge of Virgil too, for the artist has his support in supplying the son of Iasis with a forceps *"prensatque tenaci forcipe ferrum"* (l. 404). The fates would still have been against Æneas, for even Apollo lent no helping hand, had mater Venus not floated swiftly through the air from Mount Ida, in Crete, not in the Troas, where she had once dallied with Æneas' father, and brought some dittany leaves and stem, with which the goats treated their wounds and with this help from Heaven Japyx got the arrow out and the hero healed in marvelous time.

Daremberg (1b) takes note of some of these things and attempts a collection of all Homer knew of anatomy, but it is a meagre showing for the great industry and philological knowledge displayed by the learned Frenchman. With these sterling qualities it is singular he seems endowed also with a remarkably vivid imagination and one, less gifted, soon perceives that fewer anatomical notes accumulate as the result of an independent search. Most of our names for the regional anatomy of the surface of the body are derived from those of Homer, otherwise the anatomy of Homer is minimal. From him we have our words pharynx, phlebotomy, tarsus, stomach (only it was not exactly the stomach) stoma, sternum, cardiac, ischium, neural, derma, gastric and a large number of other terms, but it was left until comparatively recent times to associate any exact meaning with them. They are a part of our language, of all modern languages, like the vast body of our scientific terms, absurdly uncouth some of them, but all coming from the Greek, which some insensate men are attempting to obliterate.

John Owen's Epigrams on Medicine and Medical Men

By WILLIAM RENWICK RIDDELL, LL.D., F.R.H.S.,
Toronto, Canada.

There never has been a time when medicine and the medical profession were exempt from quips and slurs, humorous or serious, and ranging from merry banter to savage satire. John Owen (1560 ?-1622), a Welshman, wrote many epigrams, among them a number on the medical man and his art; and it is the purpose of this paper to copy a few of his epigrams of that kind. Owen was educated at Oxford where in 1590 he took the degree of B. C. L. (1): he spent most of his life in teaching: he called himself Joannes Audenus (2).

The epigrams are Latin elegiacs, and are of different lengths—most of them consist of the one couplet of one dactylic hexameter and one pentameter; others, having more than one of such couplets—I find one with eight, others six or five. The Latin is perfect (*Sapuerunt* in Lib. II, 10, is probably a misprint), the metre, good (unless an occasional hiatus be considered a blemish) and the rhythm exceptionally excellent. Eleven books containing 1,635 epigrams were published in Owen's lifetime: there are in my edition a twelfth book and some disconnected verses, published posthumously, 1.777 pieces in all.

He was an inveterate punster, made an occasional anagram (3), had some wit and much sense of drollery. These epigrams have been translated into English, French, German and Spanish; and the Latin text has been frequently republished. My own copy has the date 1819 stamped on the back; but it bears internal evidence of having been printed long before. No profession or class escapes Owen's pen: but in this paper, only epigrams concerning medicine or the medical profession will be noticed.

The translations are wholly my own—they aim to give the sense of the original and are as literal as that object and the idioms of the two languages permit: they have no other merit.

The first epigram I copy contains the prehistoric but ever new jibe that "the cure is worse than the disease." Perhaps Hood's Jack Hall expresses the thought most tersely:

> In fact, he did not find M.D.s worth one D—n.

But let us listen to Audenus, Lib. I, 20—

TO A CERTAIN NOBLE YOUTH

Everyone wishes long life to you, no one death;
Disease not medicine is desired for you.

(The Latin saying was: *Plus a medico quam a* *morbo periculi,* More of danger from the doctor than from the disease.)

Here fits in a posthumous epigram, Supp. 56:

TO CYNTHIUS

Six mortal diseases tortured me, Cynthius;
Worse than these six is the seventh, the Doctor.

The next two are characteristic of the times when purging was an almost universal practice—not a bad one, by the way, when people overate as well as overdrank so tremendously. (Lib. IV, 199.)

GOLD FROM ORDURE

Virgil drew gold from the ordure of Ennius:
Virgil, did, what the doctor does too.

Chaucer's

"doctour of physike
In all this worled ne was ther non him like
To speke of physike and of surgerie
. . . .
. . . knew the cause of every maladie
Where it of cold or hote or moist or drie,
And wher engendred and of what humour
He was a veray parfite practisour;" but, of course,
"For gold in physike is a cordial
Therefore he loved gold in special."

Owen's other epigram is not so classical. (Lib. XI, 23.)

GOLD FROM ORDURE (4)

The contractors for the public jakes gathers gold from Ordure, (5)
And two others, the farmer and the doctor.

The folly of the quest for the "Philosopher's Stone" is hit at in the next. The seekers were almost invariably physicians. (Lib. II, 9).

AGAINST THE CHEMIST

The Chemist boils inert matter when he is boiling gold,
And he wastes all his substance for *the Stone.*

It is an extraordinary fact that even intelligent people will cast up to members of the medical and other professions that they make money—why in earth should they not? (Lib. I, 21.) (Lib. I, 53.)

TO A CERTAIN POOR PHYSICIAN

You who but the other day came to our city a Mendicant, (6)
With a slight change of name have become a Medico.
You give the sick man drugs, the sick man gives you gold;
You cure his disease, he yours:

THE DOCTOR

The doctor takes gold offered, he is not accustomed to give it;
The doctor gives drugs, he is not accustomed to take them.
It is proper for the doctors Ordonner, for the sick Or donner,
So each thing demands the help of the other.

The English proverb has it, "The physician owes all to the patient but the patient owes nothing to him but a little money." In this, however, "owes" has the subjective meaning of duty, i. e., "owes all" means "has the duty in all respects." In that sense only is the proverb true. (Lib. I, 113.)

THE SURGEON

Whether should one pray for war or for peace? Either serves me:
Both Mars and Venus are patrons of mine.

Venus according to old John Gower

"is the source and welle
Of wele and woe" . . . (Confessio Amantis)

How she is a patron of the surgeon appears from the text (Lib. I, 114):

THE LUES VENEREA

Italy is my native land (7), my parents French;
The Frenchman is in doubt, let the Italian speak.

Perhaps the following contains a bitterer satire. Who Cinna was, does not appear (Lib. V, 86.)

TO CINNA, A PHYSICIAN

You know how to kill diseases: and how? you kill the sick, too.
What you do, Cinna, like Judas you do quickly; (8)
Him, who is your patient, oh thrice and fourtimes blessed man.
You do not allow to suffer from *long* illness.

Bacon's "Cure the disease and kill the patient."

Old Samuel Garth was not more sarcastic when in the dispensary he assailed the practitioner:

The patient's ears remorseless he assails
Murders with jargon where his med'cine fails,

adding.

While others meanly asked whole months to stay,
I oft dispatched the patient in a day.

The following is a different form of the better known description of the change of rôle of the doctor (9) (Lib. V. 95).

THREE-FACED ÆSCULAPIUS

The face of the attending doctor seems to be threefold
To the sick one—that of a man, a demon and a god.
When the doctor first comes in and salutes him,
The sick one says, See here comes God or my guardian Angel!
When medicine has put disease to flight he cries, There's a Man.
When the doctor asks for his pay, Get thee hence, Satan. (10)

Hence the sage advice to the medical man *"accipe dum dolet,"* "Get your fee when he is sick."

If the doctor cannot give anything else a prescription is in order—nowadays more than ever—and the cabalistic ℞ Owen thinks is "Recipe," as no doubt it is, whether or not it is also an invocation to Jupiter. (Lib. I, 161.)

TO PONTICUS

Having promised several things, Ponticus, you give me nothing;
Just as a doctor although he gives nothing, says *Recipe.*

And George Colman in his Lodgings for Single Gentlemen tells us:

But when ill indeed
E'en dismissing the doctor don't always succeed.

No sager advice was ever given than that celebrated *Gnothi Seauton, Nosce teipsum;* the invisible part of man is just now beginning to receive study by the medical profession. (Lib. V, 79.)

KNOW THYSELF

Let Ethics be added to Physic if thou desirest to know thyself;
This teaches the anatomy of the body, that of the soul.

Dietetics is not new: the famous School of Salerno in its Maxims said:

If Physicians fail you, let these three be your physicians,
A merry mind, quiet, moderate diet.

Just our proverbial "Dr. Diet, Dr. Quiet and Dr. Merryman." (Lib. II, 168.)

CONCERNING DIET, TO I. H.

If you wish to grow old slowly, you should use
Either moderation medically or the medico moderately:
Medicine taken injures health just as food does,
And food taken is as healthful as medicine.

The same thought is somewhat differently expressed in the next epigram to be quoted. (Lib. III, 57.)

INTERFERENCE

We who desire to lengthen the span of this fragile life,
Why do we shorten the way of life by luxury?
We do not and we do wish the period of life to be lengthened;
We do not wish that to be done by ourselves: we do, by doctors.

Dryden puts it thus:

The first physicians by debauch were made,
Excess began and sloth sustained the trade.
. . . .
The wise for cure on exercise depend
God never made his work for man to mend.
And plain living gives health and long life.

Lib. XI, 34.

NATURE CONTENT WITH (or full of) WHOLESOME FOODS. (11)

Do you wish to be fit? That is easy, for in stores of bread and water
Whoever wishes may be very rich.

Some medical man called "Celsus" (12) by Owen, seems to have been a better trencherman than wit. Suppl. Ep. 68.

TO CELSUS

The platters set forth tasty food, grateful to you,
And your table bears no insipid food.
But in you; there is nothing tasty, no (Attic) salt, (13)
Your platter, I think, is more tasty with viands than you.

"Celsus" does not seem to have been too sympathetic. Suppl. Ep. 69.

TO CELSUS CONCERNING HIS (14) GOUT

That gouty pain keeps me from the temple, Celsus,
Do you, smiling, venture to call it laziness?
But be it laziness, that is pardonable;
I wish that your laziness would pain you as much.

Supp. Ep. 70.

TO THE SAME

That held by the feet, I am obliged to take to my bed
Is no evil, Celsus: but mere laziness is.
But is not the sloth preventing you from going to the temple
The avarice from giving, gout both of foot and hand?

Dr. Paulinus was worse than Celsus or Cinna. (Lib. I, 44.)

TO DR. PAULINUS

Why is your sick man, Paulinus, called your *patient,*
Although he may be *impatient* of the disease and of you?
Because he suffers from you, he is called your *patient,*
For the doctor tortures him more than the disease.

But Cinna is bad enough. (Supp. Ep. 77.)

CONCERNING CINNA

Compact breaking Cinna is always wanting me to play with him.
I don't do it, for play also has rules.
There are worse things than gout in life.

Lib. I, 108.

ABOUT COTTA

When Cotta, the other day went into the warm lupanar,
He is said to have gone home, *re infecta* (15).

Lib. I, 127.

TO COSTUS

You sin with impunity but not your mentula; the other day,
Cauterized, it suffered decapitation (16).

Lib. I, 136.

TO PINOTUS SUFFERING WITH COLIC

If you had not breathed out your soul, (17) Pinotus, you would have died;
What is death to others, that was life for you.

Lib. IV, 227.

TO D. C. G.

Gout and the disease the opposite of gout, both trouble you;
Your wife makes you run, the gout makes you stop.

Health does not come from drinking healths—not to the drinker—for, as Jerome says, "We drink one another's health and spoil our own"—nor to the toasted. (Lib. VII, 14.)

WHOLESOME ANAGRAM

I wish to you much, I drink to you no health:
More effective is dry health than health drunk.

"In the multitude of counsellors there is safety," says the Wise Man: but "too many cooks spoil the broth" and "doctors differ." *"Dum medici consultant moritur æger."* "While the doctors are consulting, the patient dies." The Emperor Hadrian on his death-bed kept saying that the multitude of physicians had killed him: the old Greek epitaph has it: "the visits of many physicians have killed me," etc., etc.

But Owens puts it rather neatly (Lib. XI, 69):

THE SICK ARE NOT CURED BY NUMBERS

Believe me, a sick man will never be cured of a disease
If one fever is trusted to many physicians.

Owen is fond of comparing the legal and the medical professions, and of taking a fling at both. Sometimes, theology is brought in and fares worst of the three. (Lib. V, 11.)

THOU SHALT NOT KILL: THOU SHALT NOT STEAL.

Thou shalt not steal: this law is written for the lawyer;
This one, Thou shalt not kill, belongs to the doctor.

Arthur Clough's version of "Non occides" in his "The Latest Decalogue" may be cited:

Thou shalt not kill: but need'st not strive
Officiously to keep alive.

Lib. VIII, 3.

THE LAWYER AND THE DOCTOR

Unless the former be crafty, unless the latter be venturesome,
Both may feed themselves on begged food.

Lib. VI, 47.

THE DOCTOR AND THE LAWYER

Galen gives wealth, Justinian gives honors,
So long as the latter is not a patient, the former a client.

Lib. I, 15.

TO DOCTORS AND LAWYERS

You, Galen, are efficient in respect of our ulcers,
You, Justinian, are wise in respect of our folly.

Lib. I, 71.

KINSHIP OF DOCTORS AND LAWYERS

Lawyers and doctors stand on the same footing:
What hurts others is legitimate gain for them:
These to the ills of the sick, those to litigation over fields
Give careful assistance while they make themselves masters of the money (19).

Tacitus says, "The physician is superfluous among the healthy"; but Owen shows how to be *"sanus"* in every sense. (Lib. III, 123.)

MEDICINE AND LAW

If mortals were willing to live according to nature,
There would be no need of the assistance of Medicine.
If men were wise and they would avoid quarrels and greedy lawsuits
And the fustian eloquence of the querulous Court,
Then the ill-arranged Bartolus (20) would go behind the bookcase,
And the mouse would gnaw Hippocrates no longer read.

Brougham defines the lawyer "as a gentleman who rescues your estate from your enemies and keeps it to himself": Owen has quite as poor an opinion of both lawyer and doctor. (Lib. VIII, 36.)

FROM BAD TO WORSE

(Out of the frying pan into the fire.)

He falls into Scylla seeking to avoid Charybdis, (21)
Who fleeing the disease, falls into the hands of the doctor.
The foolish while they shun certain evils fall into the contrary ones.
Who flee a lawsuit and consult a lawyer.

In the following there is an amusing play on the two words spelled and pronounced the same: "Jus," law, private right, and "Jus," broth, infusion, our "juice." (Lib. V, 50.)

AMBIGUOUS "JUS"

The lawyer and the doctor are both skilled in "Jus,"
The latter saves the sick, the former estates by "Jus."
The lawyer has learned to give to each client his own particular "Jus." (22)
The doctor to the sick man his own particular "Jus."
How does the "Jus" of the lawyers differ from the "Jus" of the doctors,
Do you ask? That is dry, this is wet.

Now we are introduced to the theologian who along with doctor and lawyer rule the world, as did Jupiter, Neptune and Pluto, the three sons of Saturn. (Lib. I, 131.)

THE THREE SONS OF SATURN

Untrustworthy theologians (23), lawyers deliberate and crooked,
Filthy doctors—by these is the world governed.

The two Roman Triumvirates of Julius Cæsar, Pompey and Crassus, and of Cæsar Octavianus, Antony and Lepidus, are recalled by these three all-powerful classes. (Lib. X, 80.)

THE TRIUMVIRS

The physician lives intemperately, the lawyer as an outlaw:
Who are the theologians? Nothing but divine Words.

The theologian is not in good odor, notwithstanding the importance of his sacred office. (Lib. IV, 194.)

TRIUMVIRS

Clients think well to go to the lawyer:
Why, unless they think wealth the greatest good?
The sick man sends for the doctor when confined to bed:
Health of the body is the second care of men.
The theologian who should be the first to be sent for for the sick,
Comes last—but he *comes,* even if nobody sends for him.

Good advice is always in order. (Lib. IV, 226.)

THE THREE CONFIDANTS

The whole story should be told of a lawsuit to a skilled lawyer,
To the doctor, the disease; to the priest, the sins.
You who wish to save your money, soul and body,
Conceal nothing in life from these three.

This advice is proverbial in English, French, German and Italian—probably in other languages. The Italian runs:

Al confessore, medico e avvocato
Non tenere il ver celato.

Lib. X, 67.

THE THREE RULERS OF THE WORLD

Let the clergyman be wise that he may be all things to all men:
Let the lawyer be prudent and the physician skilful.

In Adam's fall
We sinned all.

the New England Primer says: John Owen puts it thus (Lib. III, 45):

ADAM'S FALL

Adam's fall subjected the soul to the theologians,
And the body to the doctors and estates to the lawyers.

Perhaps the following goes beyond the legitimate bounds even of satire (Lib. IX, 26):

CHRIST, THEOLOGIAN, PHYSICIAN AND LAWYER

Having exercised the function on earth of theologian and physician
In Heaven He will perform the duty of Judge.

Old Galen is treated with respect. (Lib. VI, 49.)

ANAGRAM GALEN, ANGEL

Whether are you a good or a bad angel, Galen?
Guardian of human health, therefore a good Angel.

When physicians are mentioned by name, they are spoken of in high terms. (Lib. VII, 65.)

TO THEODORE DEODATUS (24), PHYSICIAN

You are the Gift of God in your Greek and your Latin name:
Skilled in the art of Apollo, you will be thrice the Gift of God.

With all his satire, it is obvious that Owen had a higher opinion of the Medicine of his day than Bacon who in his celebrated *Advancement of Learning* (1623) said: "Medicine is a science which hath been . . . more professed than laboured, and yet more laboured than advanced: the labour having been, in my judgment, rather in circle than in progression." Owen highly praises another medical man. (Lib. IV, 250.)

TO WILLIAM BUTLER, CAMBRIDGE PHYSICIAN (25)

Let others seek their gains to the neglect of health
You despise the delights of gain; your care is Health.
With you as physician, no one despairs of health lost—
Just as though medicine were your own discovery.
I speak truth of you, I do not flatter you as the patient is wont to do,
Praise does not come to you, William, from the insane.

Lib. III, 197.

TO JOHN GIFFORD, MOST SKILFUL DOCTOR OF MEDICINE (26)

That you should be skilled in the art of Apollo, Gifford,
Is not to be wondered at: you know your own body.
This, indeed, Galen does not direct but the learned Apollo
Demands it! Gnothi seauton was Apollo's precept (27).

And so we leave old Joannes Andenus, latinist, civil lawyer, teacher and epigrammatist.

NOTES.

1. This required a course in the Civil Law, i. e., the Law of Rome.

2. When every scholar wrote in Latin, a Latin or Greek form was given to rude names without classical form, e. g., Gerhard Gerhards became Desiderius Erasmus; Schwartzerd, Melanchthon, etc. It is probable that the absence of the letter w from Latin induced Owen to use the consonant d, but he writes *Walliæ* for Wales, etc., without regard for classical orthography.

3. In his time and for long after, a favorite literary amusement. Owen had not William Combe's aversion to the pun.

But still a pun, I do detest
'Tis such a paltry humbug jest
They who've least wit can make them best.

Possibly the best pun in the English language is that of Burke on the name of his friend and fellow student in Kildore, Dr. Richard Brocklesby. Greeting him as Dr. "Rock" and asked why, he said: "I can prove it by Algebra: Your name is Brock—b (Brock less b) which equals Rock," i. e., Brock—B=Rock.

4. *Aurum in stercore quaerere*—to seek for gold in ordure was a familiar postclassical apothegm. See, e. g., Cassiodorous, Inst. Divin. Liter. I., 510. Ennius, born 239 B. C., the first great Latin poet—even in the time of Cicero he "was considered the prince of Roman song. Vergil was not ashamed to borrow some of his thoughts and not a few of his expressions." Ovid, Tristia ii, 424, calls him: *"Ennius ingenio maximus, arte rudis."* His works are believed to have been extant as a whole as late as the 13th Century; now, but a few fragments remain.

Tiberius Claudius Donatus in his Life of Vergil says, "Vergil when once he had Ennius in his hand, being asked what he was doing, said that he was gathering gold from the ordure of Ennius."

5. Our ordinary Latin-English dictionaries are very prim about this word "forica," e. g. Andrew's Freund translates it by office, warehouse, taking the old Scholiasts' view in the Scholia on Juvenal, Satires, iii, 38: but there can be little if any doubt that Facciolati is right in giving the meaning—the place into which we cast faces; and it seems to be properly used of a public closet, as *laterina* of a private one. The "conductor" was the contractor who rented them from the city: he sold the ordure for manure "ad Rusticos."

Juvenal, Sat. iii, 37, 38.

. . . . .inde reversi
Conducunt foricas . . . .

Juvenal lashing the low politicians says that they used to blow the horn at shows, but now they "farm the jakes" built for the accommodation of the public, upon payment of a trifle. *Conductio* is a well known word in the Roman law.

6. Mark the play on words—Mendicus, Medicus.

7. Though it is almost if not quite certain that sypilis had its rise in Europe from Italy, it was generally known as Morbus Gallicus, French Pox, etc., etc. Frascastorio, who invented the word Syphilis, called the disease Morbus Gallicus.

8. Jesus said to Judas *"Quod facis, fac citius,"* St. John, XIII, 27 (Vulgate).

Dr. Sir Samuel Garth perhaps had Owen's Epigram in mind when he wrote of his confrère and enemy, Dr. Sir Richard Blackmore, who wrote verse of a kind and whom Garth addressed as "the merry Poetaster of Sadlers' Hall in Cheapside."

Unwieldy pedant, let thy awkward muse
With censures praise, with flatteries abuse:
. . . .
The feeble satire ne'er can do him wrong
Thy poems and thy patients live not long.

9. There are several epigrams to much the same effect. I have before me an Italian epigram: it is however almost identical with and probably a translation of the best-known Latin *Sal Atticum.* Pope says: "While Roman Spirit professor of Medicine in Marburg, was the author of the wellknown epigram:

Tres medicus facies habet: unam quando rogatur,
Angelicum: mox est, cum juvat ipse, Deus.
Post, ubi curato poscit sua praemia morbo,
Horridus apparet, terribilisque Sathan.

The physician has three aspects: the one, that of an
Angel, when he is sent for: shortly afterwards, God
When his medicine is working—afterwards when he asks pay,
The disease being cured, he appears a repulsive and fearful Devil.

Cordus is probably better known by his paternity of these elegiacs than of Valerius Cordus (1512-1544) the discoverer of sulphuric ether and the author of the first Official Dispensatory.

10. *"Tunc dicit ei Jesus: Vade Satana."* St. Matt., IV., 10. Owen drops the last syllable of Satan's name that the word may fit into the pentameter.

11. A pretty ambiguity—*contenta* may be from *contendo* and mean full, tense; or it may be from *contineo* and mean contented, satisfied.

12. Of course from A. Cornelius Celsus, the celebrated Roman physician and medical author of the Augustan times.

13. *Salitus* properly means sprinkled with salt, but like *salsus* it was used in the sense of acute, witty, facetious; *sal* was wit as well as salt, and we still speak of Attic salt, Latin verses of Cordus. Euricius Cordus (1486-1535), charms and Attic Wit," and the old Greeks said. *"Halme ouk enestin auto."* There is no salt in him.

14. i. e., the author's not Celsus'.

15. An exquisite pun, because so atrocious; *re infectâ* means the matter unfinished, or without having transacted the business, here it means, with the thing (*id est mentula*) infected. The ambiguity of *infectus,* unfinished or infected, is found in Latin—it arises from the double meaning of the prefix "in," not or into.

Calidum is not applied to the brothel as indicative of the physical and pathological condition of the inmates, not so much hot as "fired," the language is borrowed directly from Juvenal's famous Sixth Satire in the description of the vices of Messalina.

16. *Supplicium capitis* is capital punishment—Caesar's *capitis poena,* Bello Gallico, VII, 71.

17. *Anima* in its primary sense means air; it is only metaphorically the soul or spirit; the pun is obvious.

18. J. C. is *Jurisconsultus,* properly Consulting Counsel —but used by Owen for Lawyer generally.

19. Note the puns—*aegrorum, agrorum; opem, opum; patienter, potiantur.*

20. A well known commentator on the civil law of Rome; he was of almost equal authority with the text of the Institutes of Justinian itself. He lived 1314-1367, and was professor of Civil Law at the University of Perugia. Owen having taken the degree of B.C.L. at Oxford must have been familiar with Bartolo's works.

Hippocrates is, of course, the Father of Medicine, read by physicians almost till our own day. It is said that the celebrated Dr. Richard Mead first recommended himself to Radcliffe by his answer to Radcliffe's surly remark when he found Mead reading Hippocrates in the original—"I never read Hippocrates in my life," said the blunt Dr. Radcliffe. "You, sir, have no occasion. You are Hippocrates himself," was Mead's courtierlike reply.

21. *"Incidis in Scyllam, cupiens vitare Charybdim"* is a line from some unknown medieval writer founded on the adventures of Ulysses in the *Odyssey*.

22. "The maxims of law are these: to live honorably, to hurt no one, to give every one his own."—Justinian's Institutes, I, 1, 3. "Justice is the constant and perpetual wish to give every one his due," do., do., I, 1, 1. Cicero in his Oration against Verres has the double pun *Jus Verrinum,* hogbroth or the justice of Verres.

23. The form *Theiologus* with the lengthened first syllable is used instead of *Theologus,* as the latter with three successive short syllables would not fit into a dactylic hexameter; when the exigencies of the verse do not require it, the form *Theologus* is used by Owen.

24. I do not know this Deodatus. There was a Claudius Deodatus, a bishop and physician in ordinary at Basel about 1629; he was a follower of Paracelsus. Deodatus in Latin and Theodoros in Greek both mean Godgiven.

25. William Butler (1535-1618), born at Ipswich (not in County Clare, Ireland, as Bass has it, *History of Medicine,* Am. Edit., p. 395, n. 1), educated at Clare Hall, Cambridge, graduating M. A. He did not take his M. D. but practised with extraordinary success; he attended Henry, Prince of Wales, in his last illness, and was held in great esteem by his father, King James I. See D. N. B., VIII, p. 90.

26. Dr. John Gifford seems quite unknown to fame.

27. Apollo, who in the words of Byron (Childe Harold) was

> The Lord of the unerring bow,
> The God of life and poesy and light.

was also the God of the healing art and was called the father of Aesculapius—no doubt, a poetic and mythical statement of the wholesome effect of the sunlight (for beyond question, Apollo was primarily the Sun).

Medical Germany

By M. R. ROBINSON, M.D., F.A.C.S.,
New York.

For the past fifty years Germany has occupied the centre of medical activities, and has attracted students from all over the world. What has made Germany the beacon light on the road of medical advance for more than half a century? What powers and forces are still maintaining for it this unique position? Why did the Americans of the past as well as those of the present go to Germany for postgraduate study, in the face of our wealth of material and our magnificently equipped hospitals?

For the Americans, this question has been succintly answered by George P. Muller (1), when he said: "Postgraduate study in America does not exist; it must be created."

It is indeed a healthy sign to see our leaders admit that something is wrong with our medical education. Our country is undoubtedly endowed with all the potentialities of becoming a medical centre worthy of the world's recognition; if only our leaders could be aroused to a keener sense of their duties and responsibilities. Americans have contributed epoch making achievements to surgery, to gynecology, and within the past decade, to biology, biological chemistry and embryology. But all these achievements were the products of isolated and individual effort. Such work has the tendency to flash our scientific horizon, from time to time, but lacks the constant glow of collective and systematized endeavor. To foster creative work, to stimulate investigation, and to enhance research, we need collective effort, so that the scientific threads picked up by one group may, without interruption or unnecessary loss of time, be taken up by their successors and woven into the fabric of medicine.

After a sojourn of nine months in several of Germany's leading medical clinics, I feel it my duty to record my impressions, hoping thereby to contribute towards the arousing of the creative spirit, so that our institutions may in the future offer to the graduates in medicine that which has been denied them, or rather, which was impossible to give them during their undergraduate period.

I shall endeavor to omit from this report as much as will be consistent with accuracy, that is, the purely academic problems of medical instruction, and devote my time to the consideration of the undergraduate methods of teaching as they are, of the teachers, of the atmosphere in which our art and science is being taught, and of the relationship that exists between the undergraduate and the postgraduate medical development and growth.

THE CHARITE.

The first thrill that sets the medical soul vibrating, as one approaches the Charite is the Virchow monument. It represents *Health* and *Disease* engaged in a fierce struggle for supremacy, in the form of two gigantic figures. The former succeeds in subduing the later with a strangle hold. Beneath these figures is a white marble relief of Virchow bearing the inscription of his full name, nothing else. This monument is impressive in its simplicity and truly represents the life and the work of the great master; who has linked theory with practice and has given to clinical medicine its true scientific impetus.

To the right of the main gate of the Charite stands the most artistically executed lifesize bronze figure of Albrecht von Graefe. Holding the ophthalmoscope in his right hand, he gazes upon two groups of people, with a mingled expression of sadness and gratification. The figures to his right are partly or completely blind and are praying for the restoration of their sight, while those to the left of him give mute though eloquent expression of their gratitude for the help already obtained. The inscription on this monument, excerpted from William Tell, is so appropriate and striking that it is worthy of repetition, it reads:

> O eine edle Himmelsgabe ist das Licht des Auges,
> Alle Wesen leben vom Lichte, jedes gluckliche Geschoepf,
> Die Pflanze selbst kehrt freudig sich zum Lichte.

Once within the gates of the Charite, the visitor finds himself in a labyrinth of buildings occupied by the various medical departments. The thrill first experienced, gains in intensity as one continues rambling amidst the galaxy of medical celebrities whose statues adorn the paths and buildings: Friedrich Althoff, von Leyden, Traube, Orth, Griesinger, Westphal, Bardeleben, König, Langenbeck, Schroeder, Robert Koch and Emil Fischer. Many more, too numerous to mention, could be added to this list, without running the risk of having included one not worthy of occupying a niche among the immortals in medicine.

From the artistic side, which embellishes and enriches the sphere of life, let us now turn to the scientific part and observe how full grown to their tasks the high priests and prophets within these temples of medicine are, and to what extent they live up to their traditions.

PATHOLOGY.

Biology, biological chemistry, physics and higher mathematics have of late contributed much towards the solution of some problems concerning body functions in health and in disease. But for a long time to come, morbid anatomy will still continue to predominate as the science of abnormal physiology. The significance and blessings of pathological study are summed up in an inscription over the door leading to the autopsy rooms, it reads: *"Hic locus est ubi mors gaudet succurrere vitæ!"*

Lubarsch and his associates, among whom Ceelen ranks highest, direct this department. The material is abundant, the autopsies complete, and the methods of teaching thorough and superb. What these teachers are aiming at is to correlate postmortem findings to clinical phenomena. They do it in so vivid, so clear, so convincing and stimulating a manner, that the student is bound to carry away with him deep and lasting impressions. Pathology thus becomes part and parcel of the whole subject of medicine, and the clinician at the bedside is prepared to have a mental picture of the structural changes that have taken place in the organ or organs which he is treating. This form of teaching pathology also serves as a lesson of the dangers that lurk in partial autopsies, and how erroneous their interpretations may become. In these schools the undergraduate is given abundant opportunity to lay a solid foundation for his immediate medical education and to rear upon it a creditable edifice if he so desires.

INTERNAL MEDICINE.

In the Berlin University this department is under the leadership of three heads, who in order of their importance seem to me to be Kraus, Hiss and Goldscheider. Their methods of teaching are chiefly clinical in nature; there are no prepared or set lectures which are being ruminated from year to year with but slight variations in the cud. The clinical material at hand forms the basis and the theme for the days' instruction. The patients are brought into the lecture room and the professor begins to analyze and discuss the given maladies. As he proceeds to unfold the clinical data, nothing that is of scientific value and theoretical importance is omitted. Every effort is being made by the teachers to make the student visualize the knowledge that is being taught through all the aids and devices that the human mind is capable of inventing.

This is the prevailing plan of instruction adopted by all the departments, so that the student receives his knowledge of the various medical subjects not as separate and independent fragments of science but as coherent and allied parts of one entire medical whole.

Not until now have I fully grasped the meaning of the word school or *Schule* in the German academic sense. In Germany a school is designated as such, not because of its geographical distinction or method of endowment, but because of its own form of creative thought which it radiates under the guidance and inspiration of its leader. It is therefore not unusual to find in the larger universities more than one so-called school in one department. The advantage of such a system is to give the student a broader viewpoint of medical knowledge and to encourage him to seek information from various sources. Here are some of these fountain heads of medical learning.

Kraus is a venerable sage, orator and scholar! How imperceptibly does he merge old well known physiological and pathological facts into the most recent advances in the realms of colloid chemistry, metabolic disturbances, dysfunctions of the autonomic or the endocrine systems. Whether he teaches the principles of percussion and auscultation, or speaks about the disorders due to calcium and potassium disproportion in the animal economy, the same thoroughness, ease and facility are noted. At times Kraus mounts to medical heights which very few can ascend, and from which he alone can, so far, see the medicine of the future. Such a form of teaching is necessary. For the function of universities is not only to prepare the hewers of wood and the drawers of water, but also those who aspire to walk the higher paths of medicine.

Hiss clings more to the practical side of medicine and teaches the more positive things. In the course of his instruction, he displays an amount of knowledge so vast and universal in extent, that the listener becomes spellbound and is rapt in attention and admiration.

Goldscheider is the living exponent of the Senator school. He emulates his master in thoroughness, keen power of observation, and great clinical intuition. Goldscheider is the most popular lecturer in medicine. His feet are always on the ground, he appeals to the minds of the average student, and tries to impart the most useful knowledge in the most assimilable way. He deals with facts; his questions are direct, to the point and the answers always follow in logical sequence. He belongs to the class of clinicians who rely more upon their own power of observation than upon the modern scientific diagnostic aids. This, however, does not imply that Goldscheider lags behind scientifically, rather, does he accept scientific innovations deliberately and carefully after they have been critically weighed in the scales of clinical experience.

GENERAL SURGERY.

There are two surgical clinics in the Berlin University, conducted respectively by Hildebrand and Bier.

Hildebrand represents the type of surgeon which is rapidly disappearing to the great loss of clinical medicine; he is not merely a mechanic, but also a thinking, reasoning physician. His operations are not of the fireworks variety, which win the plaudits of the admiring onlookers, but they consist of steadily progressing movements, well calculated and purposeful. He is sure of his anatomy, knows his physiology, is well versed in surgical pathology, is an excellent teacher and so obtains ideal therapeutic results.

Bier is a veritable dynamo of surgical originality. His mind is fertile with problems, thus forming a source of inspiration to his coworkers. He is a forceful and impressive teacher, and a highly gifted surgeon. Among his pupils, Schmieden is the most noted. He occupies at present the chair of surgery in the University of Frankfurt. I have visited Schmieden and saw him work. His clinic is a marvel of thoroughness and his technic admirable.

My impressions of German general surgery lead me to say that the training and preparation which the surgical aspirant has to undergo before he is entrusted with surgical responsibilities is far more sound and thorough than it is in our own country. In the consideration of appointments for surgical positions, technic alone is not the chief desideratum. The candidate's preliminary education in pathology, bacteriology, anatomy and experimental physiology count as much, if not more. The administration of general anesthesia in Germany is very poor and it would be to the credit of German surgeons if they would send a few of their younger men to learn the art of anesthesia in America.

GYNECOLOGY AND OBSTETRICS.

These two specialties are inseparably linked together in all the teaching centres. In the Berlin University there are two clinics represented by Bumm and by Franz.

Bumm, in the opinion of the author at least, has no equal as a teacher in these specialties. His lucidity of speech, thorough mastery of the subjects, wide experience, general information and scholastic attainments, in addition to his artistic endowments, which he brings into play in the process of teaching, contribute to make his lectures impressive, and fascinating. The surgical work in this clinic is fair, and neither Bumm nor any of his associates display surgical ingeniousness. The department of Röntgen therapy is under the direction of Warnekross who, in collaboration with Dessauer, has contributed much that is of lasting value.

The description of this famous clinic would be incomplete if I were to omit the mention of its pathological department which reflects upon it just as much glory and renown as do the other departments. Robert Meyer directs this department. His fame is international and it would be futile for me to attempt a description of what this master in morphology and embryology has contributed to the science of gynecological pathology for the past twenty-eight years. My close association with him for six months leads me to say that, to know Robert Meyer is a great privilege, to work with him a rare opportunity.

The Franz Clinic is preeminent for the surgical genius of its guiding chief. There is no gynecologist in Berlin and, as far as I have seen, anywhere else, who can equal Franz in surgical dexterity. With the precision of a mathematician he calculates every step with lightninglike rapidity, wielding his instruments with the grace, poise and alacrity of an accomplished artist, and all this is done under the control of sight, in which he is greatly helped by the excellent illuminating system in his operating rooms. His method of teaching varies from that of Bumm in being much simpler, more practical and not as all embracing. Franz wants his students to learn what is really essential to know in the usual pursuit of obstetrics and gynecology, to recognize complications in time and to obtain or render competent assistance before it is too late. The pathological department of this clinic is ably conducted by Dr. S. Aschheim, who is an excellent teacher, a fine clinician, and a most amiable personality. Of his younger assistants B. Zondek is the most promising. His preliminary training in physiological research and biological chemistry enables him to grapple with the problems dealing with pathological pregnancy, endocrine dysfunctions and organotherapy. Gynecology and obstetrics will undoubtedly be enriched by his scientific labors.

The Franz Clinic also deserves mention for the democratic spirit which it radiates, in contrast to the austere and repelling atmosphere of obsolete militarism which still lingers in that of Bumm.

The Wertheim Clinic in Vienna is another great centre of gynecological and obstetrical learning. It was not my good fortune to find the master alive. His place was temporarily filled by his ablest and most distinguished pupil, Weibel, who through some reasons unknown to me was not called upon to fill the chair as was expected by so many. Professor Kermauner is now the head of this great clinic, and what I have seen of his work behooves me to say that next to Franz, Weibel is the most skillful gynecologist I have thus far known. Weibel has also done an extensive amount of work in the field of röntgen and radium therapy. The attitude of this clinic towards the problem of irradiation or operation in uterine cancer and myoma, is the same as that of the Berlin clinics, namely to operate in all operable cases.

RÖNTGEN AND RADIUM THERAPY IN GYNECOLOGY.

The exclusive use of röntgen and radium therapy in uterine cancer and myomas is carried out with scientific exactness and clinical thoroughness in the clinics of Freiburg, Erlangen, and Frankfurt. In these clinics röntgen rays are chiefly used at times also radium either alone or in combination with x rays. The representatives of these schools are Kronig, Seitz, Wintz, and Opitz. The majority of Germany's leading gynecologists still follow the dictum of operating upon all operable cases. The question may therefore be raised as to which of these schools is in the right. From a perusal of the statistics furnished by the contending clinics it becomes evident that the curative results are equally good yet we see the pendulum swinging from time to time in favor of one group to the other. What gives rise to these clinical oscillations and vagaries? It is the variation in the sources of information from which the statistics emanate. "Statistics," Sir Berkeley Moynihan once said, "can be made to tell anything, even the truth," and indeed they do tell the truth of the observer as seen from his own angle or as the result of his personal experience; and here lies the great clinical difficulty. Into the compilation of surgical statistics the personal attributes of the given surgeon enter to a great extent and, what a skillful surgeon may consider operable, a less skillful one may consider inoperable. Besides these apparent and unavoidable clinical inconsistencies, we also encounter biological difficulties which still await a solution. We often see that pathologically similar cancers are influenced differently by the same quantity and quality of rays, or that patients suffering from identical cancers are differently affected by them or respond differently to the same kind of treatment.

In view of all these still unsurmounted difficulties, the only course left for us to pursue in deciding upon a plan of treatment for uterine cancer or myoma, is to individualize our patients and adopt such a therapeutic procedure which under the given circumstances will render the highest percentage of cures and the minimum of mortality. Only self-criticism, and an honest comparison, from time to time, of the operative with the nonoperative methods will lead to the highest efficiency.

WHO SHALL ADMINISTER RÖNTGEN AND RADIUM THERAPY?

In Germany the specialty of röntgen and radium therapy as such, is fast losing ground. The clinicians contend that since röntgen and radium rays are therapeutic agents, those who have the patients directly under their control and understand the disease as well as the diseased, are the ones best suited to administer the treatment and judge its effects. As a result of this sound and rational attitude, we find now that in each medical centre the various departments have each its own röntgen and radium outfit. There is also a central röntgenological laboratory, but this serves as a scientific clearing station where the clinicians report their results as obtained in the course of treatment, and where the biologists and the physicists analyze these observations and are thus guided to further biological research and to improvements of the apparatus.

To view the problem of irradiation therapy in a scientific and impersonal light we must admit that the highest degree of perfection in this field of therapy will be reached where the biologist, the physicist, and the clinician will act cooperatively and reciprocally.

POSTGRADUATE STUDY.

The character of the work done in the German undergraduate clinics is of such a high scientific standard that graduates may for the rest of their lives return periodically to these mainsprings and always find an abundant supply for replenishment, rejuvenation, and invigoration.

But the function of Germany to foster and promote postgraduate study does not halt here. Every university clinic is ready to extend privileges to graduates to pursue original research or to further develop their clinical usefulness. In the Kaiserin Friedrich house, lectures on all medical subjects and allied sciences are delivered three times daily. The profession at large is welcome. The lecturers are recruited from the large staffs of ordinary and extraordinary professors. Those who cannot attend may obtain copies of the procedures for the asking and in this way the members of the profession are kept in constant touch with the most recent advances in theoretical and practical medicine.

Another striking fact which, in my opinion, accounts for Germany's supremacy as a teaching centre, is the willingness of their leaders to teach. No man considers himself too important to spend some of his time in directing or guiding those who seek information.

Besides the university clinics and laboratories there are a number of similar private institutions. The leaders of these excathedral schools are men who, having worked under and with masters for many years, finally branch out for themselves establishing their own platforms and preaching their own medical gospels. The architectural appearance of many of these clinics makes a very unfavorable impression upon Americans in particular for they are far from being models of sanitation and comfort. But what monumental work has emanated from many of these places! I saw the place where Pappenheim did his work on the blood; where Oppenheim taught the world neurology; and where Michaelis is still engaged in enriching the science of physiological chemistry. All these structures are old, dilapidated, and unhygienic. Evidently knowledge does not always seek gilded halls for its abode, and the humblest dwellings may become its hallowed shrines.

RÉSUMÉ.

1. Germany's adoption of a standard system of medical education permits its students to pursue their training in more than one school, thus lending breadth and color to their professional development.

2. The fundamentals in medicine are taught with a thoroughness that beggars comparison. The major subjects are imparted to the student, not as something separate from the whole of medicine, but as parts of it through the clinical method of teaching or, as Osler called it, "The natural method, which begins with the patient, continues with the patient, and ends with the patient."

3. Group medicine, which greatly agitates and perturbs the minds of the modern American clinicians will never take root on German soil. Germany's leading clinicians have trained themselves, and continue to train their successors, to be clinicians in the full sense which this term implies. A very apt definition of a clinician, or of how a real clinician should practice, was recently described by H. A. Royster; it reads as follows: "Let us first take a look at the patient; use our minds in obtaining a history; perform a laying on of hands; after which we will ask for the aid of scientific apparatus which may either confirm or reject our observations. And if the laboratory findings do not agree with the clinical signs, then so much the worse for the laboratory." This is the conception of clinical medicine which our older clinicians have had, and to this dictum the German clinicians are still adhering closely. Group medicine in Germany is considered as a confession of clinical inferiority for it tends to hinder the development of the clinical art. Neither Germany, nor

any other European medical centre, will lend its support to a form of practice which is subject to the schematic plans drawn in the laboratory. Clinical medicine demands individualization, and now more than ever before should this truth find expression. The patient as such must always remain the focus and centre of our biological thinking, and this is not possible with methods which call less and less upon the exercise of our clinical intuition and sagacity.

4. Each school in Germany has as one of its greatest and prime functions the training of future teachers and in this sublime duty to future generations each medical leader takes his part with pride.

5. The effect which the late war has had upon Germany is chiefly economic. Its scientific life it seems has not only regained its prewar calm, but has gained in renewed vigor. There is much that German medicine can offer us. Are we not going to accept it? Political boundaries should not stand in the way for science does not recognize them and the most eminent thinkers of the world have clasped hands across them. Let us extend our friendly arms to these earnest workers; let us encourage them and be stimulated by their example of devotion to science for science's sake.

William Edward McGuire, M.D.*

By BEVERLEY R. TUCKER, M.D.,
Richmond, Va.

The medical profession of Virginia feels, as the American Therapeutic Society undoubtedly does, a sense of personal loss in the death of Dr. William Edward McGuire, which occurred in Richmond, Va., on October 6, 1921.

Dr. McGuire came from a long line of distinguished American ancestors who in turn were descended from a prominent and virile clan, the McGuires of central Ireland. Dr. McGuire was born in Berryville, Clarke County, Va., in 1860 and was a cousin and brother-in-law of our fellow member, Dr. Stuart McGuire. He attended school in Berryville and in 1886 graduated in medicine at the University of Virginia. After his graduation and the completion of some postgraduate work he began the practice of medicine in Richmond and remained there until his death. He occupied the chair of gynecology, then that of clinical medicine at the University College of Medicine, and later the chair of clinical medicine at the Medical College of Virginia. He held various positions of trust and was at one time president of the Richmond Academy of Medicine. He was also a member of the State Board of Health of Vriginia, a volunteer in the medical service of the U. S. A., a Fellow in the American College of Physicians, a member of the International Gastroenterological Association, the American Therapeutic Society, and of many smaller societies.

Early in his professional career Dr. McGuire practised both surgery and general medicine, and it was said of him that he was "an old fashioned family doctor with the methods of a modern physician." In the later years of his life, though he never entirely gave up his family practice, he became noted as an internist and diagnostician.

It was said of him at the time of his death, by the editor of one of the Richmond newspapers, that "no man in his generation had been more loved in Richmond than Dr. Edward McGuire. Endowed with the gift of medical perception which often amounted to pure intuition, Dr. McGuire never trusted to mere natural ability. The easy course was never the course that appealed to him and in the midst of an enormous and exacting practice he took time to keep abreast of the modern developments in the field of medicine. All the amazing growth of technic Dr. McGuire made tributary to his practice, and to science he added experience, so that, with his medical gifts and his wide opportunity he made of the new knowledge a hand maiden and not a tyrant. It was his loyalty to his patients that gave him among physicians a distinctive title—he was not Dr. McGuire to Richmond; he was Dr. Ned."

It is to his personality and character that I especially desire to pay tribute. I only wish that mine was the power to pay it adequately. Many men have been successful practitioners and scientific physicians but he had added to these qualities a character which was a tower of strength and a personality which made him genuinely and generally beloved. Dr. McGuire lived through a period when professional antagonism and animosities were the order of the day, but through it all he maintained the admiration and respect of all factions. In all things he was a man of sound judgment, deliberate action, clear conception, conscientiousness and moral courage. He was broadminded and benevolent and his criticisms were without malice. His service to his profession and his patients was untiring and his knowledge was wide but at the same time accurate.

At the age of sixty-one he came to the end of his life, a life full of rich experience but cut short by his unsparing sacrifice to work. For years he had a kidney condition which was at times very painful and which he knew was incurable, but he never complained and he never gave up. I am glad that I had the privilege of knowing "Dr. Ned" and that the members of this society had the privilege of knowing him. He was a gentleman of the old school who greeted us with kindness and a courtesy, whose words could be depended upon, whose opinion, though valuable and modern, and backed by experience, was never egotistical or obtrusive, and we think of him as a man whose example we should like to emulate.

212 West Franklin Street.

Editorial Articles

THE QUEST OF THE UNKNOWN

"In the teeth of the outrageous, the absurd disabilities imposed on him, Man, the imperfectly denatured animal, who cannot trust the evidence of his own senses in the simplest matter of fact; whose evidence on the simplest matter is colored by his own iniquities; Man, always the hunter, went up against the darkness that cloaked him and every act of his being, to find out what order of created being he might be. He called it scientific research. It was the old quest under a new name. But this time the seekers who headed it, unlike the priest and the lawyer, admitted that they knew very little. Experience had taught them to be humble. For that reason their knowledge was increased. They moved forward into areas of the body, which, till then, had denied themselves to Man's hand. They were turned back, without explanation, from other areas which, as yet, would tolerate no spying. They were bewildered by mysteries which, under some new mirage of observation upon accident or some predestined slip of the knife, resolved into—mysteries profounder still! Is it any wonder that all the old dreams came back? The dream of the essential unity of all created things—the dream that some day that which men called life might be led into matter which men called dead—the boldest dream of all, that eventually Man might surprise the ultimate secret of his being where Brahm had hidden it, in the body of Man. And, meanwhile, their days were filled with the piteous procession of men and women begging them for leave to be allowed to live a little longer, upon whatever terms."

The address of Mr. Rudyard Kipling at the dinner given by the Royal College of Surgeons after the Hunterian Festival on February 14th last adds to the understanding tributes which have been paid to that body of seekers whose quest is the relief of suffering and the prolongation of life. It is more than praise, it is a psychoanalysis of the very spirit of medicine and the urge which energizes its patient, selfless search for truth. Man, according to Mr. Kipling, is "an imperfectly denatured animal intermittently subject to unpredictable reactions of an unlocated spiritual area. And it is just this search for this unlocated spiritual area, whether it be a growth or a survival, which has preoccupied Man. The priest and the lawgiver have probed and fished for it all through the ages; but, more than any other, through all the ages, the leech, the medicine man, the healer, has been hottest on its track."

Ever the elusive search moves onward. Just as we seem to be about to touch upon its mystery, new horizons unfold before us. Undismayed we hopefully push ahead, always reaching out for the infinite, jealously guarding our little store of half understood, half mistrusted facts, firmly believing that the unattainable will be soon achieved.

A GREAT BRITISH SURGEON

The really great surgeons of the world may be counted on the fingers of two hands; perhaps, on the fingers of one hand. As Sir Frederick Treves says in a book published recently, the great surgeon is born, not made. A great surgeon died on March 15th last. Sir William Thorburn is referred to. At the time of his death he was emeritus professor of clinical surgery at the University of Manchester.

The son of Dr. John Thorburn, professor of obstetrical medicine at Owens' College, Manchester, William Thorburn was born in that city in 1861, received his medical education at the Manchester Royal Infirmary, afterwards attending various hospitals of London. He had a distinguished career as a medical student and took the degrees of B. Sc. and M. D. at the University of London, obtaining the gold medals and winning a scholarship. He was elected to a fellowship of the Royal College of Surgeons in 1886, and was appointed assistant surgeon to the Royal Infirmary, Manchester. He quickly made a reputation for the treatment of injuries of the spine, injuries which occur frequently in a manufacturing area like Manchester and neighborhood, where machinery is used largely. Up to the time that Thorburn devoted his attention to this subject, little notice had been paid to it. However, he made use of the numerous opportunities which came his way to such purpose that in 1890 he was awarded the Jacksonian Prize for an essay on The Nature and Treatment of Injuries to the Spinal Column and the consequences arising therefrom. He also made these injuries the subject of a course of lectures he delivered as Hunterian professor of pathology and surgery at the Royal College of Surgeons of England. Indeed, he so made the question his own that he came to be regarded as the leading exponent of and authority on this branch of surgery, not only in Great Britain but throughout the world. In December, 1922, he chose it as the subject of his Bradshaw Lecture and summed up his experience of fifty years or thereabouts in a somewhat despondent fashion. But at that time he was a thoroughly depressed man and this fact must be taken into consideration.

His outlook on life was gloomy. At the outbreak of the war he was already holding the rank of lieutenant colonel in the R. A. M. C. Territorial Force, and was at once placed in command of the Second Western General Hospital. His three sons were killed in the war. He was appointed consulting surgeon at Malta, Gallipoli and Salonika, and in 1917 he filled a similar position in France. For his services during the war he was given a C. B. in 1916, and a C. M. G. and military K. B. C. in 1919, while during his stay in Malta he was given the honorary degree of M. D. by the University of Malta.

From 1913 to 1923 he was a member of the Court of Examiners at the Royal College of Surgeons, and he also served as an examiner in surgery at the University of London. In 1914 he was elected a member of the Council of the College of Surgeons. Lady Thorburn died in the autumn of 1922, a blow from which he never recovered. Thorburn was, as are so many great men, of modest, gentle and unassuming nature. However, he was of a strictly scientific mind, of strongly formed opinions and withal a persuasive speaker, and he exercised a good deal of quiet influence. He retired from active work a short time ago, but he was so broken in spirit and health by the events of the war and the death of his wife that he felt he had nothing left to live for, and although he struggled bravely the zest for living had gone, and the effort was too much for him. He was a man who deserved well of his country and science and was an honor to his calling.

CURES FOR PNEUMONIA

Much has been published recently in the lay press concerning the beneficial effects in pneumonia of external applications of heat, by means of lamps or electric currents. Unfortunately there is no statistical evidence that the assertions made for results obtained are based upon more than the usual optimism accompanying the use of a novel therapeutic agent, and, possibly, some fortunate results not connected with the treatment. In at least one series of cases, in which it was stated that excellent results had been obtained, the patients were of the type in which the best progress would be expected.

But is there anything new in such treatment? The application of external heat, in the form of poultices of various kinds, has long been practised, but with doubtful success. These measures, at any rate, have had no effect in proportion to the amount of heat afforded and a pneumonia jacket or plain shirt seems to have answered the purpose as well. The heat from a lamp is of precisely the same kind as that from an electric pad, or, for that matter, from a wet poultice. As for penetrating heat, the temperature of the body is already raised to 104° or so, which is certainly hot enough for any good results. Why attempt to add to it?

To expose the affected side of the chest to radiant heat, the patient must lie upon the unaffected side, which is surely not a good mechanical procedure. Any claims made for effects produced by electric currents or by certain rays of light are problematical indeed.

We are reminded that a few years back claims were made for great results from the open air or cold air treatment of pneumonia, but actual figures showed that the results were the same, whether the patient was treated out of doors or in. An effective treatment of pneumonia, or better still, a means of preventing pneumonia, will be of the utmost importance, and we trust that these much heralded physical means will be given a thorough trial. We feel, however, that there is nothing to justify any very optimistic hope of their effects, and it is a pity that the reports of highly successful accomplishments should be broadcasted through the lay press before there is any certain ground for such statements.

THE EDUCATION OF BOYS AND GIRLS

The proper education of the rising generation is a most important matter, for upon it depends, to a large extent, the future of a country. The definition of a proper education is perhaps impossible to give as ideas of what constitutes this vary considerably in different countries and among different classes of society in the same country. The American ideal of education is perhaps of a practical nature, one which will fit its possessor to hold his own in the battle of life.

In Great Britain, although views are changing, the ideal of education has been to form character rather than to inculcate knowledge, and a great deal of the knowledge imparted, that is, in the higher class schools, is of a character that Americans would regard as of the most useful kind. But classics are not the bugbear of the big British schools they used to be and as a matter of fact education therein partakes more now of the American flavor than was the case some few years ago. Coeducation is not so common in Great Britain as in America. The true ideal of education of both sexes is to develop both mental and physical powers and not one at the expense of the other. And this statement applies to girls as well as boys and, perhaps, more especially to girls.

In Great Britain there was published recently the report of the consultative committee on differentiation of the curriculum for boys and girls, respectively, in secondary schools. It will be futile within the scope of an editorial article to attempt to more than touch upon some of the most salient features of the report and these features will be those that concern medical evidence taken before the committee with regard to the education of girls. The committee, in view of the medical and other evidence, urges with considerable force that the pace of education in girls' schools should be carefully adjusted to the strength and opportunities for study which may be presumed of the average pupil. Not that they plead for any special consideration or lower standard of achievement for a socalled weaker sex; as they are convinced that given the same conditions girls can match the achievements of boys. But the conditions of health are not the same, and the freedom from other demands is much less for girls than it is for boys. Warning is given against overorganization. The increased *esprit de corps* in school life and the growing tendency to organize and emphasize all school activities are modern developments which stand in need of criticism and control, more particularly in girls' schools. The special danger of girls' schools is that they may become excellently organized and conscientiously loyal groups composed of mediocre and uniform units. Which means that plenty of play and scope for individual effort should be allowed.

However, so far as the health of girls at school is concerned, it is the question of games and physical exercise which is of the greatest import. It is supremely essential for the future of the race, that girls should be in such condition that they can bear and rear healthy offspring. Whatever the modern woman may say to the contrary, it is this function of woman that distinguishes her and it is of greater importance by far than anything else she may or can do. Because a woman is well educated and good at games is no reason why she should not be a mother. But if overeducation or overexercising at games is likely to injure her in this respect, then education and games should be modified.

With regard to games for girls the committee says: "Most witnesses, including several parents, thought that the general conscientiousness of girls extended also to their sports and that there was danger that some pupils, who were overconscientious and docile, might exhaust themselves physically and mentally for the supposed good of the school. There was general agreement that special care was required in organizing games for girls in day schools, and more especially in coeducational day schools." The committee suggests in the light of the evidence given before them that the whole question of games in day schools for girls and in coeducational day schools requires further investigation. While they think that suitable games should form a part of the ordinary curriculum for girls, they are not convinced that they should be made compulsory for all pupils, particularly in day schools. Hockey, lacrosse, tennis and cricket for girls were favored by most witnesses, but not football.

Commenting on the susceptibility of girls to fatigue, the committee says that their physiological evidence and a large part of the evidence from teachers, indicate that girls are, on the whole, more liable to physical and mental fatigue than boys. This may be due, not only to the larger reserve of strength possessed by boys, but also to the greater power of resisting pressure. It is well known that most boys, especially at the period of adolescence, have a habit of "healthy idleness," and are thus able to protect themselves from overpressure, whereas girls are more amenable to authority and more industrious. This is an inherited trait, probably due to generations of subjection more or less, although the committee does not say so. However this may be, the girl's greater docility and industry deprive her of some of the protections which the boy enjoys. The committee, therefore, thinks that, on the whole, the traditional arrangement by which the number of hours spent in school and the amount of time actually devoted to many subjects is shorter in girls' schools than in schools for boys is probably based on sound reasons, and that it is inadvisable to have the girls' time table too much like that of the boys. Among the recommendations offered by the committee is one for greater freedom in the curriculum in boys' and girls' schools; that time tables should be modified to allow boys and girls more free time in which to develop their own individual interests. Another recommendation is that more attention should be paid by parents, headmistresses, and school doctors to the possibility of taking suitable precautions for the protection of girls against physical fatigue and overstrain.

The report is instructive and interesting and only goes to show that the saying of Sir Almroth Wright is true, that woman is hampered by her physiological disabilities, that is, if she desires to compete with man, with the reservation that civilized woman is meant. Rough games are bad for girls, in that they may prejudice the chances of motherhood in some and thus be harmful to the race. Also such games tend to coarsen them and to impair their special feminine qualities. The modern woman will characterize the last sentence as old fashioned nonsense, but it is a point of view to which, perhaps, the majority of men incline. There is one point in the education of boys and girls to which sufficient heed has not been given, namely, that in the education of both sexes either in school work or in games, the personal equation is not considered as it should be. "What is one man's meat is another man's poison" is true in this particular. Neither boys nor girls should be made to play games unless a doctor thinks the game suitable for them and, of course, this remark may be emphasized as regards girls. Moderation in all things is an excellent maxim and quite applicable to the education of boys and girls, in school work and games alike.

SUGAR AND ALCOHOL

It was said by more than one writer in American medical journals, and the subject was especially emphasized in the editorial pages of the *Medical Record*, that when prohibition came into force the consumption of candy and sugar, in general, would be increased. This has been the case, and the question arises as to whether it is altogether so great an advantage as most people think. Given the choice between sugar and alcohol, there is no doubt which does the greater harm, but sugar, unless used discreetly, is by no means the beneficial food which some of its ardent advocates have declared. Indeed too much sugar is largely responsible for the early decay of teeth and disorders of the gastrointestinal tract.

A peculiarly appropriate editorial on the question appeared in the *British Medical Journal*, March 24th last. It appears that the British Chancellor of the Exchequer may have to make a choice between a reduction of the tax on sugar and a remission of the duty on beer, or this was so at the time the editorial was written. The writer of the editorial, therefore, discussed the matter from the physiological viewpoint. As a matter of fact, from the purely physiological point of view, neither alcohol nor sugar can be esteemed essential to the human dietary, and, of course, from the economic aspect they are luxuries. From the dietetic and caloric viewpoints the value of alcohol is considered now to be almost negligible, and the esthetic and anesthetic properties of alcohol cannot be expressed in terms of food value.

But, as was pointed out, if it is difficult to defend the virtues of beer and other forms of alcohol physiologically, it is equally difficult to defend sugar on the plea that it is a food of high value for children. It is only infants in arms who depend on sugar as the source of their carbohydrate supply, and this is merely because their capacity for converting starch has not yet been properly developed. As all starches are ultimately converted into sugar by the efficiently working human machine, and as starch is infinitely cheaper than sugar, it is more economical by far to consume starch than sugar. Moreover, sugar suffers from a disadvantage not possessed by starch. It is readily digested and absorbed so that when ingested in undue quantities it may pass into the blood more quickly than physiological conditions require and thus do more harm than good. Insoluble carbohydrates have not these drawbacks and, as said before, are a great deal cheaper. The agreeable taste of sugar may in itself prove a pitfall to the young, inducing children to eat of it to excess with serious pathological results.

Another British writer, Dr. Harvey Campbell, has no hesitation whatever in asserting that sugar eaten in large quantities by children has an extremely pernicious effect, and many well known dentists assert that eating saccharine substances to excess has ruined many teeth and digestions. Our ancestors were healthy without sugar and it has been in prevalent use in temperate climates only for a comparatively short time. Its value in the form of candy from the physiological and dietetic aspects has been grossly exaggerated and there is no doubt that taken in excess it is harmful to health.

There is no doubt that American children and even a large number of adults eat much more sugar than is good for them. This is not to say that candy should not be eaten by children or adults, but discretion should be observed and children should not be allowed to gorge themselves with sweetstuffs. At any rate, we have done our duty editorially in demonstrating that from the strictly physiological and dietetic points of view sugar is not a necessity.

COFFEE

When medical men think of coffee they involuntarily divide it into two divisions: one, the active principle, caffeine, which is a valuable therapeutic agent, and the other, to which they give little thought, ordinary coffee, cups of coffee. Throughout the world we find coffee drinkers and tea drinkers fairly evenly distributed. Here in cosmopolitan America, where old world influences have formed customs, coffee drinking predominates. In certain sections of the Orient and in the Balkans, the coffee is prepared Turkish style, finely ground with the grounds left in the bottom of the cup. Small cups of this sweetened beverage are consumed at different times of the day. The more common preparation of coffee here calls for a generous sized cup which may be prepared in many different ways. Percolation is a method which is fast gaining in favor.

Many neurotics receive with gladness the tale of the harmfulness of coffee. They eagerly welcome innocuous substitutes, coffee minus the caffeine, or some nauseating cereal preparation. They think by avoiding coffee they cure their nervous condition. This whole question has been exaggerated. Coffee in moderation does not produce nervous ailments. Removal of coffee from the diet does not cure them. Coffee with cream and sugar is a source of food and energy. In many cardiac and nephritic conditions there is no better or simpler preparation than well prepared coffee. It is amusing to see chocolate, cocoa and even tea substituted for coffee in various nervous or other conditions, when as a matter of fact the amount of stimulus cup for cup is the same or even greater. What foundation there is for giving children and old persons various chocolate preparations in place of coffee is difficult to determine.

It would be well to look at the coffee question squarely and not cover the situation by inane avoidances. Coffee is one of the mainstays of our rapid civilization. Those adults who wish to live and enjoy life, let them drink their coffee in peace. Those who wish to ascribe illness or nervousness to magical causes, let them abandon it.

PUBLIC HEALTH LECTURERS

Dr. S. Dana Hubbard, director of the New York City Bureau of Public Health Education, writes in the *Monthly Bulletin* of the Health Department an article giving some valuable directions and suggestions to lecturers on public health. If the advice given by Dr. Hubbard were followed, in part even, audiences at lectures of this kind could probably be doubled, to say nothing of increasing the amount of information and benefit received by those attending them. "The health talker is permitted to use every resource," says Dr. Hubbard, "poetical license not excepted, to insure that every hearer will become possessed of at least one clear fact of hygiene. Misinformation, exaggeration or deception are never permissible. There is no speaking platform more punctiliously accurate, and where the speaker must 'watch his step' more carefully than that of the public health forum. The truth is always demanded. The truth only should be given. . . ."

The following simple rules for giving health talks are among the suggestions made by Dr. Hubbard: 1. Be punctual at your appointments and keep to schedule. 2. Always be announced; let the introducer state your subject and inform the audience who you are and what has been your experience. 3. Adapt yourself to your audience; show that you understand their everyday problems and trials; be sympathetic; in your remarks, encourage all to aim high and help, in so far as is possible under the circumstances; with the uneducated or uninformed be definite and decided; uneducated persons are not intellectually able, as a rule, to appreciate nice scientific balancing of facts and theories. 4. Show that you practise what you preach. 5. Never read your speech; never speak from full notes; have, if you must, a rough outline of headings of your topic, but trust mostly to the inspiration of the moment and the sudden opportunity. 6. Never talk too long; a prominent pastor was advised by an eminent statesman that "few souls are saved after twenty minutes." Nothing is more tedious, especially to manual workers, than a lengthy, long drawn out speech; a short, snappy talk of ten minutes often gets over where a half hour harangue gets blocked. 7. Encourage questions; interruptions, even, are very helpful, oftentimes, in health work; if the audience appears bashful or diffident, stir up one or two individuals in the group by talking directly to them, or through them to the group; it might be well to prearrange to have some prominent person start the questioning when you are ready; a few minutes devoted to general discussion oftentimes brings out a splendid reaction. 8. Repeat and reiterate again and again; do not be afraid of repeating your statements; to test this, read some well written propaganda; you will find the subject repeated, time and again, but always in different phraseology.

CHILD SUICIDE SINCE 1918

In the recently published annual report of the Save a Life League, an organization, with headquarters in this city, which works toward prevention of suicide, some rather appalling figures are given, showing that, since the war, suicides in this country among children have nearly doubled in number. The figures quoted are based upon official reports, which means that the actual number of such suicides, if known, would make the quota much higher.

The report states that since 1918 the number of suicides in the United States among children is 3,000. In 1918 the figure was 477; in 1922 it was 900. The youngest suicide was five years old; the oldest, a great great grandmother, more than a hundred years old. In some parts of the country the figures seemed to indicate a sort of suicide wave or epidemic. A girls' suicide club was discovered. The average age of boy suicides was sixteen years; that of girls, fifteen. The boys' most prevalent method was the revolver; that of the girls, poison. A large proportion of the alleged reasons for the act were unbelievably trivial and foolish. One girl left a note saying that she was going to kill herself "to get a new thrill." A boy shot himself "for the fun of it." Another girl committed suicide because she did not find her newly bobbed hair as becoming as she had expected.

The report lists among chief causes for this state of affairs, intolerable home conditions, temperamental disorders, faulty school systems, and, most important, the large and increasing number of child marriages. In 1920 the number of boys married at fifteen was sixteen hundred; of girls, twelve thousand. Of these, records show that five hundred were divorced or widowed.

Dr. George B. Shattuck Dead.—On March 13, at his home in Boston, Dr. George B. Shattuck, for many years editor of *The Boston Medical and Surgical Journal*. Dr. Shattuck was born in Boston in 1844. Some years ago he made a trip to Central Africa for a scientific study of the health and mode of living of primitive peoples.

Dr. Lorenz Opens Free Clinic.—Dr. Adolph Lorenz, the Austrian surgeon who operates without the use of a knife, opened a free clinic at the Health Department, 505 Pearl Street. He treated many persons with physical bone defects and also a few cases of infantile paralysis. The clinic will continue every Monday until Dr. Lorenz sails for his home.

Medical Care of New York School Children.—A bill which will provide medical and dental service for all public school children of New York is at present before the legislature. This bill has a clause appended, however, that such medical and dental care afforded by the schools does not limit the power of parent or guardian to determine what treatment or correction should be provided for their children.

American Doctor Appeals for Aid for Russia.—At the annual meeting of the American College of Physicians which was held in Philadelphia last week, a letter was made public from Dr. H. O. Eversole, member of the Commission on Russian Relief, in which he made an appeal for funds, medicines, medical literature, etc., for use for medical aid in Russia. After hearing the letter the American College of Physicians endorsed the appeal.

New Jersey Academy of Medicine Auditorium.—On the twelfth anniversary of its organization, the Northern New Jersey Academy of Medicine celebrated the dedication of a new auditorium having a seating capacity of four hundred at Newark. Dr. George E. deSchweinitz, president of the American Medical Association; Dr. John M. T. Finney, of Johns Hopkins University; Dr. James Hunter, president of the Medical Society of New Jersey, and others attended the formal dedication.

Physiotherapy.—The next course of instruction in physiotherapy will be given at Walter Reed General Hospital, Washington, D. C., beginning October 5, 1923, and continuing for a period of four months. It is open to women who have had at least two years of training in an approved school of physical education. For further information apply to the Commanding Officer, Walter Reed General Hospital, Washington, D. C., attention Department of Physiotherapy.

Suicides in 1922.—Seventy-nine millionaries were among the 12,000 persons who committed suicide in 1922, it was reported by Dr. Harry M. Warren, president of the Save-a-Life League. One third of those who killed themselves were women, the oldest a great great grandmother, one hundred years old, and the youngest a child of five. Among others in New York there were thirty-eight college students, fifty college professors and school teachers, nineteen preachers and leaders of religious work, fifty-two judges and lawyers, eighty-four physicians, one hundred presidents and heads of large business concerns, and a number of bank presidents, one of whom tried ten times to die before succeeding.

Sleeping Sickness Again Reported.—The Public Health Service at Washington announces a total of 575 cases of encephalitis lethargica for the first three months of 1923. The disease was most prevalent in the week ending March 3rd, sixty-nine cases being reported. The total for the week of March 31st was thirty-seven. Public health officials pointed out that the figures were not exact. Since the germ of the disease has not been definitely isolated, physicians in a number of cases have confused the affliction with meningitis and other diseases. One case recently reported as "sleeping sickness" turned out to be coma resulting from a mastoid infection. Dr. Burton Harris, a Brooklyn surgeon and for four years secretary of the Medical Society of Kings County, recently succumbed to the disease.

Epidemics Spread Among Refugees.—Typhus and smallpox epidemics in the refugee camps of Constantinople are spreading. Pauline Allen, of Boston, American Near East Relief worker, was stricken with typhus and is in the American Hospital. Douglas Quirk, editor of the only English daily newspaper published in the Near East, contracted smallpox. Mme. Ali Bey, wife of a prominent Turk, died from typhus. Six physicians have succumbed to typhus while attending refugees.

Personal.—Dr. Charles Gottlieb, of 210 West Seventy-ninth Street, sailed for Europe on March 31st. A farewell dinner was given in his honor by his students at the Hotel Astor on March 28th. At this time there was organized the Manhattan Röntgen Ray Society. The following officers were elected: President, Dr. Charles Gottlieb; vice-presidents, Dr. J. S. Smul and Dr. H. Reinstein; secretary, Dr. L. Neuwelt; treasurer, Dr. Lesoff; historian, Dr. M. Spinrad; members of the executive committee, Dr. M. Beegel, Dr. B. Goldstein, Dr. T. B. Weinberg, Dr. S. Gellert, and Dr. J. Abowitz.

Hospital Hotels for New York City.—Plans have been filed with the Bureau of Buildings for the construction of a twenty-two story fireproof hospital hotel that is to be erected on the northwest corner of West End Avenue and Seventy-second Street by a syndicate of New York surgeons and physicians headed by George R. Hall. The building is estimated to cost $1,000,000. The hospital hotel will have four hundred rooms exclusive of four large operating rooms. The ground floor will have a two story lobby and a public dining room. There will also be extra dining rooms, and each floor will be equipped with serving rooms. The vacant property at the south corner of Fifth Avenue and 103rd Street has also been taken as a site for a tall hospital hotel which will provide all the comforts of the finest hostelry in the city. A group of physicians have purchased the property in the name of the Physicians' Medical Hotel Corporation. There will be twelve stories in this hospital hotel and will cost close to $2,000,000.

Courses of Instruction in Pulmonary Tuberculosis Under the Auspices of the U. S. Veterans' Bureau.—By authority of the Director of the U. S. Veterans' Bureau a preliminary course in pulmonary tuberculosis has been given in twenty Veterans' Bureau Hospitals. The course is for the instruction of physicians in the Bureau service. Those who have completed the course are eligible to attend the postgraduate course now being given, and to be repeated at intervals, at Veterans' Hospital No. 41, New Haven, Conn., and at Fitzsimons General Hospital, Denver, Colo. These latter schools began March 1st and 5th respectively. The chief instructor of the New Haven School is Dr. Nathan Barlow, of the Public Health Service. The Denver School is in charge of Major E. H. Bruns, M. C., U. S. A., Chief of the Medical Service. The instructors in the New Haven course are not only tuberculosis specialists connected with the Public Health Service and the U. S. Veterans' Bureau, but well known specialists not in the Bureau service.

The general supervision of both the preliminary and the postgraduate courses is in charge of the Clinical Director of Tuberculosis in the Central Office of the Bureau, Washington, D. C.

VIENNA LETTER

(*From our own correspondent.*)

VIENNA, *March* 30, 1923.

FIRST IMPRESSIONS.

The first thing which struck me in Vienna as quite extraordinary—compared to what I was used to see on my numerous prewar visits to Vienna—was the great number of really welldressed women wearing good shoes, silk stockings, latest model dresses. Who—I asked myself—paid for all these expensive things? Surely not the women out of their earnings as shopgirls, clerks, typewriters, stenographers, or cooks? For their wages were hardly enough to pay their board. I soon found out that it was the numerous class of *Schiebers*—war profiteers—who so lavishly paid for the socalled love bestowed upon them by their *lady friends.* I merely state this, with no intention of casting any reproach on the *lady friends,* nor on their *Schieber* friends. The girls saw all the luxury displayed by their sisters of the upper classes, wives of bankers, manufacturers and rich merchants, kept in great style not by the incomes of their husbands alone—such incomes could never have borne that tremendous expense—but by their one or more socalled gentleman friends. The display of furs, silks and jewels by those Messalinas in the boxes of the grand opera, at concerts, theatres and American barrooms, was outrageous. How should a poor girl —not having enough to eat at home, or fuel to keep her from freezing—not have fallen prey to such temptations if she had beauty to sell. The misery and suffering of many years of war, the loss of fathers, brothers, and sweethearts turned the girls and boys into a lot of pleasure maniacs. Their only aim was to get joy out of life at any price!

The gentleman friends most sought after were the refined looking foreigners, the swell members of the various missions sent to Vienna to exact the war reparations or to help the suffering poor. Dollars, francs and lire were the golden calves adored by the weaker sex. I was appalled at the spread of sexual diseases and sexual perversities in a community which hardly knew, before the French and Italian invasions, what perverted sexuality meant.

In this connection I might mention that legal abortion has been brought before the congress several times and laid on the table. Nevertheless, abortions are practised in Vienna nowadays by nearly every surgeon or gynecologist—a thing scarcely known in prewar times. I am told, in fact, that it is a considerable source of income. The city authorities acquiesce, because they realize that there is not enough food for the babies already here.

Vienna always was an easygoing, pleasure loving city, as the great poet Arthur Schnitzler classically depicted it in the *Anatole* and other works. But what the moral squads unveiled was not half so bad as what the clinics published in the way of statistics.

I do not, however, wish to cast any stones upon the war profiteers either; many of them I came to know personally. They are a set of physically healthy individuals, who have had the wits and grit to take quick advantage of an economic constellation. They had the brains to adapt themselves instantaneously to changed surroundings and conditions, and because their efforts were successful, they were hated and looked down upon by those who remained inactively highbrowed and were still relying upon their social distinction, inherited from their monarchistic fathers. A large number of these aristocratic pilgrims went under; another part—following the law of survival of the fittest—took up useful jobs and saved themselves.

The most pitiable of all were the academic middle classes, the real pillars of former socalled culture; they were penniless, and still refused to do manual work. For instance, I happened to take up quarters in a villa belonging to a former chief of the health bureau of one of the provinces of old Austria-Hungary. This man, whom I knew thirty years ago as an able assistant at one of the renowned internal clinics, was glad to come back to Vienna and accept a minor position in the health bureau in Vienna. Vienna has had to employ many thousand of government employees of the former monarchy to keep them from starving, because the new, independent states would not retain them; hence the incredible number of two hundred and fifty thousand government employees for six million people! His two girls, eleven and thirteen years of age, did not—out of pride—take the good square meal provided at one of the American kitchens for school children, but ate cooked beets twice a day at home, all the week round; the odor permeated the house. And their mother—the daughter of a general—would try to contribute to the household expenses by giving one or two singing lessons a week. The house was as filthy and dirty as a tenement house, because the lady of the house would not do menial work, nor could she pay for a capable servant; and when spring came, the garden was not spaded for potatoes and vegetables, but the one little girl would run about all day with a tame hen in her arms, and the other little girl with a lapdog.

In generalizing such helplessness, some explanation may be found for the misery of the middle classes, though I grant that I have seen others do hard work, home industry, *petits points,* weaving gobelins, and support themselves decently by the help of the *Werkbund*—a sort of woman's exchange.

THE NEW ATTITUDE.

While the Viennese people were always a happy go lucky set, an easygoing lot, or, as they term it here *gemütlich* (a word for which I can't find an exact translation), the disaster which has befallen them in the shape of the dismemberment of the old monarchy, cutting off the rich provinces which once supplied Vienna with all the necessities of life, has rendered them entirely helpless. They are not capable of aiding themselves; they always hope something will happen to save them, that help will come from the outside. To me their *Gemütlichkeit* always implied mental laziness, *Denkfaulheit,* as I often pointed out to my old school friends here. Take, for instance, their charity work. A case in point is their life saving station (*Rettungsgesellschaft*), a sort of ever ready ambulance service used for picking up accident cases on the streets or in the homes, and quickly transferring them to the respective departments of the various hospitals, after giving first aid. This institution, founded by a really magnanimous benefactor, Dr. Munk, some forty years ago, has proved of great value to the entire population. It is supported by private charity. When it was in great financial distress a year ago—and this happened quite often even before the war—all the papers appealed for contributions. Little help was forthcoming because everything was left to volunteer subscriptions and the newly rich were not yet aware of their plain duty toward the community in which they had amassed their fortunes. *Noblesse oblige* might now be changed into money obliges, money having taken the place of former nobility. The institution came near closing its doors. Charity work here is not organized as it is in the United States. I made an appeal for one dollar from each member of the American Medical Association of Vienna, and in five minutes' time had some forty dollars, which we delivered to the institution. Incidentally, we made a few public remarks as to the necessity for organizing their drives better. Later we heard remarks like "Those Americans should not talk so much. What's a dollar to them?"

As regards their methods here, a few prominent people contribute, have their names mentioned conspicuously in the papers which accept the contributions—and the bulk of the silent misers entirely fail to contribute.

Take another instance. The poor of the city need fuel; the municipal authorities distribute blanks to the porters of every house, and on these blanks the inhabitants of the houses are supposed to put down their names and the sums contributed. In the house where I lived I noticed on the blank the names of people who were immensely rich, owning factories in Czechoslovakia, with one thousand and two thousand kronen respectively opposite their names. And the price of a streetcar ride was fifteen hundred kronen!

During the war, scandals took place in connection with the Red Cross drives; people with high sounding names had absconded with money collected for the poor wounded soldiers. This unwillingness to help themselves has become so rampant that Mr. Avenol, the delegate from the League of Nations, made the public statement a few days ago that Vienna has done short of nothing in the line of reducing the large list of State employees. Half of the quarter million State employees are, I wager to say, merely salaried loafers. By way of illustration, I may mention that there was a small pile of dirt on the street I pass through. Four men were needed to carry it away, one pulling the handcart, another sweeping, a third shoveling the dirt into the cart, and a fourth giving orders! The same system prevails in all branches of the administrative machinery. Unless the economy dictator is invested with absolute authority, he will have a hard time combating the various political bosses, who back thousands of those paid loafers.

There was another thing which struck me from the first day I entered Vienna—the people in the street cars, palefaced and shabbily clothed, sat quietly and read books, but never laughed or talked. This was very different from the times before the war! Then, you could always hear them chat or laugh, or crack some funny jokes; now, nothing of the sort. They were like cattle being led to the slaughter house. They were irritable, at the same time; any little platform incident, such as one man stepping on the toes of another—due to the crowded condition of the cars—would start a vehement quarrel. To the physician their skin appeared to be of a peculiar paleness and transparency—no redcheeked faces, no barrelshaped men or women. One of the professors of internal medicine, of international fame, told me that during the last years of the war, when there was such scarcity of meat, Graves's disease so prevalent before, entirely disappeared. He saw no case for years at his clinic; but later on, when meat was again obtainable, the disease reappeared. He also quoted Professor von Noorden, who wanted a chlorosis patient to demonstrate to his students, but was unable to find even one among hundreds and thousands of dispensary patients. Chlorosis must surely depend upon virginity, he thought, so the former disappeared with the latter!

On my frequent walks through the suburbs, out to the beautiful bills surrounding Vienna, I noticed many schoolchildren, well fed, well dressed all carrying tin pails containing their dinner, given them at the American Relief Stations established in every school. This American Mission has fed four hundred thousand schoolchildren a day, for the last two years. Such goodlooking, welldressed youngsters, in such numbers, I never saw in the times before the war. But this story has a reverse side. While working in the clinical wardrooms, seeing many a case of liver cirrhosis, Bright's disease and early arteriosclerosis, I naturally always inquired about the quantity of alcoholic beverages ingested in the course of a day. "Well, Doctor," came the answer, "I don't drink much lately. I can't afford it." "Tell me how much, anyway!" "Well, only eight to ten pints of wine—before, of course, I had more money and drank as many quarts."

These patients were the fathers of the youngsters I had admired in the suburbs. The middle class man, lawyer or doctor, could not afford to drink one glass of beer a day, but this workingman, whose three to six children were being taken care of by the relief action, could well afford to spend his earnings in drink; so much the more so because his wife frequently took in washing and thus supported the household. Those very laboring classes are the best-paid people in Vienna. A shoemaker earns four million kronen a week, a metalworker six millions, while many a practising physician of thirty years' experience will hardly earn one to two millions a month. And if the physician complains to the workingman, his patient, about the poor pay, the latter will ask, "Well, Doctor, why did you not learn something decent?" (authentic story). On hot summer evenings almost everybody in former years used to go to the suburban vineyards and take supper out in the open, to listen to the lovely Viennese popular songs and to drink a glass or two of *Heuriger* (wine of last year's vintage). Now, one sees the working classes only, the middle classes being unable to pay the price.

The American tourist might easily get the impression that his nation is admired and beloved above all others coming here. Yes, to some extent, as long as he is willing to spend his dollars freely. But right down in their hearts the people hate and loath the American. I never could understand this attitude, in the face of the tremendous, good work Hoover and all our other relief societies have done over here. A little incident that occurred during my membership in the Physicians' Club, to which most of the lecturers (*docent*) and professors of the Medical Faculty of Vienna belonged, elucidated matters to me more plainly. While taking my five o'clock coffee with a number of my former schoolmates—a good many of them now lecturers and professors at the faculty—one of them asked me why Americans don't do this or the other thing for Austria, and so on. To my reply that I thought Americans had done a lot more for Vienna than any other nation, came the retort, "They could do ten times more and still not feel it. And if they did a hundred times more, they could never undo the wrong they have done us by getting into the war. We should have won the war if it had not been for the Americans. They have brought on us all the misery we are suffering now; they did it out of greed, not to save us from tyranny."

It was plain to me now that their cringing gratitude, shown in public for every little gift coming from America, was the fawning of a beaten dog. It was positively disgusting to me to listen to the "Hurrahs!" raised at the weekly medical meetings every time the hundred or thousand dollar gift of this or that American was announced. I knew the current which ran underneath those hurrahs. In their attitude towards everything American, these academicians differed not a bit from that of two little girls, clad in rags, to whom I spoke on the first autumn day of 1920, on one of the streetcars leading to the woods of Vienna. These undernourished girls, twelve and fourteen years of age respectively, were going out to gather wood for the winter. When I asked them if they got enough to eat at the American Relief Station, they replied, naïvely, "We would not eat that stuff. We found a long hair in the beans! We don't need the Americans, it's the *Sheenies* who make us poor!" The young children, of course, spoke as their parents did. And when told that the good clothes they had at home, as well as the good food which was given them, were to a great extent contributed also by the savings of American Jews, they answered, "Oh, yes, those are different Jews!"

This brings me to the anti-Semitic movement in Vienna. While I was aware of the fact that wherever there are Semites, there must also be anti-Semites—while I knew that for decades past, Vienna has had a political party, called the Christian-Socialists or German-Nationalists or what not to cover the name of anti-Semites, it was brought home to me in a new and poignant manner during my first call on Professor Eiselsberg, a man known all over the world for his surgical achievements. He received me with the utmost cordiality and affability, led me to his private room at his clinic, and exclaimed, after the usual conventionalities had been exchanged, "You see, my friend"—pointing to the examination certificates of six students whom he had just examined—"this is the cause of all our misery. Out of six students, four are Eastern Jews." I was at a loss to understand how a scientist of his standing could pass a fair judgment upon the surgical skill of students, if the race to which they belonged was more important to him than their qualifications. And this is the man who was in charge of the relief work for the three thousand five hundred physicians of Vienna, seventy per cent. of whom are Jews.

I may here mention a funny story that was told me about this old man. During the war, Dr. G., one of his pupils, was reported to have been killed in action. Professor Eiselsberg was very sorry about it, and stated that Dr. G. was the only Jew whom he had intended to make his assistant. Later, it turned out that Dr. G. had not been killed, but was captured in Russia, and—*nolens volens*—Professor Eiselsberg had to make him his assistant on his return from captivity. Dr. G. now has the distinction of being Eiselsberg's only Jewish assistant—the only Jew at the surgical clinic.

Similar conditions exist at most of the other clinics. It is very difficult for Jews—no matter what their qualifications and scientific achievements may be—to obtain appointments as clinical assistants, lecturers or professors. In past years many of the most able members of that race took to baptism in order to gain admission to a career which had been pronounced, by law, to be open to any citizen without distinction of nationality, race or creed. While I never could understand how a few drops of water could change the biological racial instincts and characteristics, it evidently did help many Jews to become internationally famous as professors at the Vienna University. We need only recall names like Sonnenfels, Glaser, Bamberger, Kaposi, Mautner, Lieben, Fleischl v. Markow, Stoerk, Oser, Seegen, Dittel, Goldschmiedt, Buckerkandl—men of Jewish extraction, to whom statues have been erected in the Hall of Fame in the beautiful university building. In memory of Sonnenfels, the descendant of a Jewish rabbi named Lipman, another statue has been erected in front of the City Hall—evidently out of respect for his untiring efforts to do away with the medieval instruments of torture. Then there have been other Jews at this university, to whom no monument has as yet been erected, but who certainly do possess one *aere perennius* in the hearts of scientists all over the world: Theodor Gompers, Josef Unger, Eduard Suess, Budinger, Szanto, Hirschfeld, Grünhut, Wiesner, Politzer, and Zeissl. Julius Wiesner, the plant physiologist, was once rector of the university. H. S. Chamberlain, the highest authority on racial anti-Semitism, dedicated his book on *Foundation of the Nineteenth Century* to this Jew. The three renowned brothers, Adolf, Franz and Siegmund Exner—two of whom served as rectors of the university—had a Jewish mother.

It cannot be denied that Jews have played an important rôle in the development of the country's civilization, and have pressed themselves to the front in many branches of science instead of leaving precedence to the non-Jews. Josef Unger, Glaser and Grünhut had great influence upon the development of jurisprudence; Steinbach regulated the Austrian money system; Kelsen created the Constitution of the Austrian Republic, while Friedjung, Pribram, Josef Redlich, Wertheimer and Charmatz have well nigh monopolized the history of latter day Austria. Josef Redlich is considered the classical teacher of English constitutional administration, and is known to every American.

The only Austrians who ever obtained the Nobel prize were Jews—the pacifist Fried, and the ear specialist Bárány. For the latter, there was no place at the Vienna University, so he accepted a chair at a university outside Vienna. Think of the founder of otiatry, Politzer; of Winternitz, who originated hydrotherapy; of Stricker, who created experimental pathology; of Dittel's urology; of Freud's psychoanalysis; of Benedict the neurologist! Think of Behring, the discovered of diphtheria antitoxin; of Ehrlich, who discovered salvarsan, and we must all admit that Jews—ever since their first healer, Jesus, became known—have given proof of a peculiar racial instinct for the art of healing the sick.

(*To be continued.*)

LATIN AMERICA LETTER

Balboa Heights, C. Z., *March* 25, 1923

SANITATION IN THE CANAL ZONE.

The Panama Canal, a strip ten miles wide running from northwest to southeast across the Isthmus of Panama, has excellent sanitation, as have also the terminal cities of Cristobal-Colon and Balboa-Panama, but so far as the interior of the republic is concerned, relatively little has been accomplished. The central government, it is true, has maintained a series of small hospitals and dispensaries in the capitals of the provinces under the direction of physicians who are known as *medicos officiales,* and the International Health Board has established an uncinariasis service, but there is no national health agency and no plan of a concerted health movement. Vital statistics are rather indifferently collected and morbidity data almost not at all; many localities are scourged with malaria which renders their inhabitants subnormal from infancy to the grave; ankylostomiasis and other parasitic intestinal infections are prevalent and widespread; from time to time alastrim smallpox sweeps through the provinces and many of the oldest cities in the New World have degenerated into filthy, insanitary hamlets. But while little direct attempt is being made to meet these conditions, they are being improved, not by intention but as a byproduct resulting from the installation of good roads with increased opportunities for social and commercial intercourse.

The change which has taken place as a result of doing away with the isolation in which the interior communities formerly lived is almost unbelievable. Not only is civic pride being awakened and municipal cleanliness being increased, but cities which were centuries old enemies are now erecting sanitary cooperative abattoirs. Sanitary markets are being built; sanitary privies are being used; public water and lighting systems are being installed. The economic benefits of improved opportunities for the shipment of agricultural products are manifest in the increased prevalence of shoes—the arch enemies of the hookworm—and the way in which the automobile truck is supplanting the oxcart. It is planned to connect Porto Bello with Colon by a modern road and a movement is now on foot to induce the United States to erect a wagon bridge across the Canal so that the western half of the Republic will not be cut off from the capitol by American property. That this would be of enormous benefit to the health and prosperity of Panama there can be no doubt, since the results of what has already been done are so apparent.

GEOGRAPHY OF PANAMA.

The geography of the Isthmus of Panama is extremely puzzling to most visitors and since every year the number of physicians touring the Canal Zone is increasing, it seems as though some mnemonic expressed in medical terms might prove useful. If a person imagine himself lying on the world with his toes at the South Pole and his left arm reaching up to touch the United States, his body will take the relative position of South America, his left arm that of Central America, and his left clavicle that of Panama. The Isthmus is clavicular in outline and joins with Colombia—the sternum—to the eastward and Costa Rica—the left shoulder—to the westward. But it is a clavicle which has been fractured and on its posterior surface there is a callous—Punta Mala. At the point of greatest convexity is the northern end of the Canal—the Isthmus runs east and west—and at the point of greatest concavity and a little nearer the midline of the hypothetical body is the southern end. At the north are the two coterminous cities, Cristobal Colon (Christopher Columbus) and at the south two more, Balboa-Panama.

DR. BEEBEE'S EXPEDITION.

Among those who composed the exploring party which went through the Panama Canal on the Yacht *Noma* on March 23, 1923, was Dr. James F. Mitchell, of Washington, D. C. The expedition is headed by Dr. Beebee, curator of birds of the Metropolitan Museum of New York, and will visit the Galapagos Islands for the purpose of making studies and collections of both marine and terrestrial life. The yacht will return to Balboa by way of Guayaquil about May 1st.

FOOT AND MOUTH DISEASE IN CENTRAL AMERICA.

On account of the reported prevalence of foot and mouth disease in Honduras and Guatemala and the contiguity of Salvador, Nicaragua and Costa Rica to those countries and the reported overland interchange of cattle between them, the chief quarantine officer, Dr. W. C. Rucker, issued an order on March 14, 1923, prohibiting entry into the Canal Zone or the cities of Panama and Colon either permanently or for transshipment of certain animals and things liable to carry the infection.

PANAMA MEDICAL ASSOCIATION.

The program of the 196th meeting of the Panama Canal Medical Association, which was held on March 23rd at Ancon Hospital, was supplied by the Board of Health Laboratory Staff, a valuable paper on Laboratory Findings from the Typhoid Group Over a Period of Fifteen Years being presented by Dr. Wesley C. Cox and discussed by Dr. D. P. Curry, Dr. L. B. Bates, and Dr. V. H. Cornell. The schedule of programs for the balance of the year is as follows: April, Surgical Service at Ancon Hospital; May, Health Department; June, Santo Tomas Hospital Staff at Santo Tomas Hospital; July, Panama Canal Department, Medical Corps, United States Army at Quarry Heights; August, Medical Service at Ancon Hospital; September, Herrick Clinic at Panama Hospital; October, Corozal Hospital Staff at Corozal Hospital; November, Staffs of Colon and Good Samaritan Hospital at Colon Hospital; December, Medical and Surgical Service at Ancon Hospital.

Book Reviews

LIFE OF LAWSON TAIT

Lawson Tait, His Life and Work. A Contribution to the History of Abdominal Surgery and Gynecology. By W. J. Stewart McKay, M.B., M.Ch., B.Sc. New York: William Wood & Co., 1922. Pp. xii-579.

The author's aim in this biography was to show that his teacher, Lawson Tait, was the founder of modern abdominal surgery, at the same time recording the steps in the evolution of gynecology. The work of Tait is correlated with that of his contemporaries. With a book of this sort a true perspective of former years may be gained and it is an illustrious example of how the history of medicine and surgery may be learned by reading the biographies of the most prominent figures of a certain period. Owing to the author's close association with Tait, he was enabled to give first hand information, based on personal observation of the master and his work.

Tait's contribution to surgery include an active campaign against the prevailing excessive hospital mortality; the first deliberate removal of the ovaries for pain and a study of the diseases of the ovaries; abdominal hysterectomy; the treatment for chronic inversion of the uterus; cholecystotomy; the V and H methods of doing perineorrhaphy, in the latter of which he emphasized the necessity of suturing the sphincter muscle in complete rupture of the perineum; a uterine elastic dilator; hepatotomy for hydatid cyst; the intraperitoneal treatment of the pedicle of the ovarian cyst; pelvic drainage in suppuration and its pathology; the pathology of ectopic pregnancy and its treatment; the surgical treatment of chronic inflammation of the uterine appendages; an artery forceps; ovariotomy; work on cyst of the urachus; the modern principles in the surgical treatment of ectopic pregnancy; some advanced ideas on antisepsis and aseptic surgery and gallbladder surgery. Tait was a prolific writer and he engaged in many heated controversies on the moot surgical questions of his day. His influence on American surgery is traced. The second part of the book deals with his method of operating and some anecdotes and events in his private life.

On the whole, this book will prove to be an excellent pastime for the leisure hours of the physician: it is written in an interesting style and the material is instructive. There is a dearth of works such as this, which serve a purpose all their own. The living personality of the master is reproduced.

EFFICIENCY

The Successful Physician. By Verlin C. Thomas, M.D. Philadelphia and London: W. B. Saunders Company, 1923, pp. 303.

In these days of intense competition, not only among physicians themselves but between the regular physician and the practitioners of all sorts of cults, pathies and isms, the publication of books like this is highly desirable and even necessary. Dr. Thomas has aimed to provide a guide book for the traveler along the highway to professional success, and points out what he considers the straightest and best paved roads to the goal of the medical practitioner.

The author emphasizes the fact that a book of this kind cannot make the blunderer efficient, nor can it make the misfit fit. It can, however, help the reader to avoid the errors that others have made before him, inasmuch as it is based on a large experience. The young physician entering on the practice of his profession realizes but too quickly that his real professional life differs essentially from his career at college and in the hospital. The world expects and demands efficiency and makes no allowance for youth and inexperience. He finds very quickly that it is necessary for him to know how to meet his patients and how to handle them; he must familiarize himself with accepted professional methods of practice and follow along certain lines of modern life which apply to all social activities, but especially to the physician.

This volume is intended to furnish these teachings, and contains a vast fund of information and many suggestions which must inevitably tend to make the physician a more fully rounded and thoroughly up to date member of his profession and of the community in which he lives. Special articles by experts in life insurance, investments, legal matters, court practice, office systems of accounts, etc., add materially to the practical character and value of the work. The volume can be commended as a most useful contribution to the practical side of medical practice.

ANATOMY OF THE BRAIN

Anatomie des Grosshirns. Foranalytische Untersuchungen. By Dr. med. E. Landau. Mit 66 Figuren im Text. Bern: Ernst Bircher Aktiengesellschaft, 1923. Pp. viii-146.

With the author we thank the publisher of this book for its attractive form, which is most suitable for enlisting and holding the reader's interest. For its material is well worth such an introduction. Landau's own clear, well arranged presentation also stands in the service of a comparative study of great value. He has discussed the formation of the brain and cranium and their mutual relationship, has submitted the development of the convolutions and fissures of the brain to an extended comparative examination. The basal ganglia have been likewise the subject of study and the development of the island of Reil as it has been sought out in many lower animal forms. Work of other investigators with their theoretical conclusions has been freely taken into consideration. The author has adhered to his guiding principle that only observable facts form sure morphological ground. Causes must be considered only as theoretical, to be treated therefore with fearless willingness to modify one's conception of them or simply when necessary to leave them to the still unknown. He makes a fruitful comparison of older and more recent points of view in regard to biological questions which arise out of his researches. He is content to leave certain things in question, but insists upon his belief that developing forms do not proceed directly one from another but rather together each in its own way from a primitive general type. It is well to forget for a time that "ontogeny repeats phylogeny" and get back to a more varied range of facts which dispute the literalness of that dictum.

PSYCHOLOGY OF RELIGION

An Introduction to the Psychology of Religion. By ROBERT H. THOULESS, M.A. New York: The Macmillan Company, 1923.

An attempt to study the psychology of religion by an inclusion of the modern psychological methods of approach. The writer shows a wide and superficial knowledge of dynamic psychology and a familiarity with modern socalled conservative Christian religions. Primitive religious impulses are given inadequate consideration. Psychopathological impulses are attributed to socalled mysteries and an attempt is made to prove that more conservative religious beliefs are true sublimations of libido impulses. The libido which Thouless prefers, naturally, is the one described by Jung. Throughout the work a sincere effort has been made to face psychological problems as presented by the most radical schools. The book is well written and will undoubtedly find favor among many who are inclined to be liberal minded.

STUMPS AND ARTIFICIAL LIMBS

Artificial Limbs and Amputation Stumps: A Practical Handbook. By E. MUIRHEAD LITTLE, F.R.C.S., Eng. With 267 illustrations. Philadelphia: P. Blakiston's Son & Co., 1922.

The reader of this work will undoubtedly marvel at the fact that it is possible to make so interesting a book on so prosaic a subject as stumps and artificial limbs. The author has succeeded in presenting his subject in a manner which is at once instructive, illuminating and fascinating. He has not attempted to offer a complete and encyclopedic work on the subject, but has contented himself with an exposition of British practice with few references to foreign methods, which, he believes, differ little and often not advantageously from British methods. In a book dealing with stumps and artificial limbs, there is always present the danger of converting the work into a limb makers' catalogue; but in the present volume, the author having had this possibility in view, has tried to avoid it, with a considerable measure of success. On the whole, the work is one which must be of considerable value to the orthopedic surgeon as well as to the unfortunate individual who requires the artificial limb. It can be followed with safety and confidence by those who are interested in the subject with which it is concerned.

JAPANESE RESEARCH

Mitteilungen aus der Medizinishen Fakultät der Kaiserlichen Universität zu Tokyo. xxviii Band 1. Heft. Tokyo: Verlag der Kaiserlichen Universität, 921. Taisho x. Pp. 197.

A. Imamura reports his investigations on the metabolism of the Japanese wild turkey under varying conditions of life, especially during hibernation. The glycogenic function of the liver, muscles and the rest of the body and the blood sugar, fat and respiratory quotient both during activity and during hibernation are carefully studied. Tomizo Watanabe reports a case of microcephalus, in which the important changes in the brain, both gross and microscopic, were studied in detail. S. Tachigara reports on the biological significance of hyperglycemia after the intravenous injection of typhoid bacilli in rabbits. He investigated the changes in temperature, the changes in the blood sugar concentration after the intravenous injection of the typhoid bacilli in normal and immunized animals and after the intravenous injection of Witte peptone, the changes in blood sugar concentration after the splitting up of the peptone in the body by the intravenous injection of heterogenic erythrocytes, the significance of blood sugar in relation to the splitting up of the typhoid endotoxin and anaphylotoxin from the injected typhoid bacilli, the results of injecting large amounts of typhoid bacilli into rabbits rendered hyperglycemic, the gycolysis of the blood after the injection of typhoid bacilli, the development of nucleated erythrocytes in the rabbits rendered hyperglemic, the effect of glucose on the complement and the biological significance of the blood sugar.

FRIEDMANN'S TURTLE BACILLUS

Die Friedmann Methode. Kritisch Beleuchtet unter Berucksichtigung der gesamten Friedmann-Literatur. von DR. VICTOR BOCK. Mit einem Vorwart von Geh. Rat PROF. DR. F. JESSEN-DAVOS (Schweiz). Leipzig: Verlag von S. Hirzel, 1922.

The book represents a summary of all of the literature which has appeared concerning the turtle bacillus treatment of Friedmann. It is called a critical review but actually confines itself to uncritical praise of the remedy. The treatment has been sufficiently discredited by the leaders in the study of tuberculosis in Europe and America to make further discussion unnecessary.

X RAY THERAPY

Strahlentherapeutische Monographien aus dem Frankfurter Universitäts Institut für Physikalische Grundlagen der Medizin. Band I: Zur Therapie des Karzinoms mit Röntgenstrahlen. Vorlesungen über die Physikalischen Grundlagen der Tiefentherapie. Von o. ö. Prof. Dr. Fr. Dessauer. Zweite verbesserte Auflage mit 32 Textfiguren. Band II: Dosierung und Wesen der Röntgenstrahlenwirkung in der Tiefentherapie vom physikalischen Standpunkt. Von Prof. Dr. Fr. Dessauer; mit 6 Textfiguren. Band III: Biologische Grundlagen zur Strahlentherapie der Bösartigen Geschwülste. Vorlesung gehalten von Professor Dr. W. Caspari, Leiter der Abteilung für Krebsforschung am Staatsinstitut füe Experimentelle Therapie in Frankfurt a.M., mit 1 Kunstdrucktafel. Dresden and Leipzig: Verlag von Theodor Steinkopff, 1922.

This series of monographs on röntgenotherapy, written by the well known Dessauer and his associates, is exceedingly valuable. They are a series of lectures given by these writers and were published in response to a demand by their friends and pupils for a short and intelligible treatise on the subject. Three volumes have already been published: the first volume consists of four lectures on the physical bases of deep röntgen therapy of carcinoma and an appendix describing the author's (Dessauer) publications from 1905 to 1914 and a bibliography of articles written from 1915 to 1921. The second volume, also written by Dessauer, treats of the dosage and nature of the action of x rays in deep therapy and is very practical. In the third volume Caspari discusses the biological principles of röntgenotherapy of malignant tumors. The fourth volume (not yet published) is to be written by E. Pohle and Jarre and is intended to discuss the practical method of treating carcinoma. Additional volumes will be published later.

STEKEL

The Homosexual Neuroses. By Dr. William Stekel. Translated by James S. Van Teslaar, M.D. Boston: Richard C. Badger, 1922.

Sex and Dreams. By Dr. William Stekel. Translated by James S. Van Teslaar, M.D. Boston: Richard C. Badger, 1922.

These two new translations of Stekel will be welcomed by students of human behavior. *The Homosexual Neuroses* is a continuation of *Bisexual Love* which appeared some time ago (Badger) and is one of the best things Stekel has done. Stekel is always stimulating and if one can discount his impetuosity, which at times leads him to be dogmatic, much can be got from a study of his better things. Many of his works have appeared in English previously but most of these were his attempts to popularize the study of modern psychopathology. These earlier translations are not altogether sound in their deductions and it is fortunate that his more worthy works are now appearing.

Sex and Dreams gives a series of sketchy case histories and some of the dream material presented. The interpretation of the dreams may be criticized on the ground that no adequate reason is given for the conclusions presented and that other interpretations may have been overlooked. This latter point is one that can be taken regarding any interpretation of dreams that may be cited. Nevertheless there are points of great value.

In Stekel's discussion of homosexuality, he takes the extremely logical stand that it is a normal biological process being an integral part of the bisexual picture shown in normal development. He does not include another important mechanism—that of primary identification as the outcropping of Freud's most fundamental ego, libido or narcissistic component. It is well to remember that human behavior is exceedingly complex and that no one thing is responsible for any attitude that may be taken. If Stekel's works are read from this critical approach they will prove of value. The only danger lies in falling into his fallacy of attributing certain reactions to definite and limited causes.

PLAYS OF PESSIMISM

The Waltz of the Dogs. By Leonid Andreyev. New York: The Macmillan Company, 1922.

East of Suez. By Somerset Maugham. New York: George E. Doran, 1922.

There is little of sunshine or goodness in Andreyev's dramatic play *The Waltz of the Dogs.* The plans of progress, the attempts at construction, formulated by those portrayed in the play all founder on the rocks of evil, cupidity and sadistic lust. Not a worthy character remains in the lot when the final curtain falls, from the best intentioned to the ones who were chronic rotters. Evil grows from evil, evil grows from good. This seems to be the final philosophy of the gloomy Andreyev. A fair concept of the Oriental in the Slav cannot be obtained here.

* * *

Maugham weaves his plot for *East of Suez* in that most Oriental city Peking. The danger of a play of this kind is that a people may be judged from the portrayal of certain dramatic, psychopathological characters. This danger exists because we must form our opinion from works such as Maugham's which serve to portray countries and races symbolically. We do not have opportunity to study any group of persons in these far off countries. We must therefore refrain from concepts which may tend to prejudice. The dramatist naturally cannot be blamed for his selection of incidents for he like the newspapermen seeks the unusual. It would be just as fair for a dweller in a far distant country to judge us by our most colored daily papers.

Maugham's play is tense, full of thrills and action. It is filled with destructive goals just as is Andreyev's play. Here, too, evil feeds evil and evil destroys the good. The Oriental differs little from us. This we may best prove by his mental states, he has the same conscience we have—the same loves—the same hates. He differs from us in certain minor standards, which have been established by him and by us to conform with certain external conditions. Yes—he has the same emotions and, more important, suffers from the same mental diseases. This, after all, shows us how nearly alike we all are underneath our externals.

DREAMS AND REALITY

The Goose Man. By Jacob Wassermann. New York: Harcourt, Brace & Co., 1922.

A reviewer spoke of this book somewhere as the effort of genius to live beyond the dictates of the world. It is, and it isn't. Genius creates its own world, but rarely tries to live in it. The unhappy Gooseman, Daniel Nothafft, longs for a little of the world's genuine love and happiness. It is denied him. His genius receives the tacit blame. The living, breathing world that Wassermann pictures with such appalling veracity is befuddled by Nothafft's constant dreams. Reality has no place in it. All the lives in the book jar and beat against the sharp angles of reality like chips in a swirling current—and this makes the book singularly true and singularly valuable to the student of human motives.

This vast symbolic representation of the ever present conflict between reality and phantasy is not easy to put within hard and fast limits. It is a creation, a source of never failing new thoughts, appreciations. One finds from day to day new applications, new meanings. It enthralls with the touch of the master. And we can only dimly understand.

When it comes to the concrete figures of our weaknesses, foibles, vices, with which every city is filled, we can understand them only too well. A great many pathological characters interweave this story. There are as many about us every day but we are not trained to see them; to see those phases in them that have warped them from companionship with reality. Daniel Nothafft reeling from one stunning blow after another, alone retains his creative sanity in an insane world. To his fellows he is, of course, the only unbalanced member of the community. Thus is it always.

This book is unusually valuable to the physician because of the commonplace traits which are brought into such sharp relief that they appear as they really are—dangerous abnormalities. They border so closely upon what we are accustomed to expect, that our vision has become dimmed. It needed this ruthless emphasis to show us what reality, hidden beneath the ever protective disguise of outward appearance, actually is.

Medicoliterary Notes.

In the *Nation's Health* for March, Dr. Douglas A. Thom, now of Boston, has an article on Habit Clinics for Child Mental Problems. These clinics aim to treat the misunderstood, often asocial child, before he has a chance to undermine the foundations of family life.

* * *

The *New Republic* has evidently realized the great need for medical information of the proper kind in suitable form for popular consumption. The series of excellent articles that have been running for several weeks by Nicholas and Lillian Kopeloff is helping to supply this need. The last is a discussion of the drug evil in the *New Republic* for March 7th.

* * *

An interesting account of medical progress in Samoa since the war is given by one of the medical staff in the *New Zealand Medical Journal* for February.

* * *

The State Charities Aid Association is distributing an appeal that those who approve of the Antin-Cole Bill, now pending in the Legislature, make this fact known to the Senator and Assemblyman who have sponsored this bill. It makes provision for State aid for special classes in the public schools of New York State. All who are interested may obtain the text of the bill and a memorandum in its support from the State Charities Aid Association, 105 East Twenty-second Street.

* * *

Health Equipment in Framingham, Then and Now, is the title of an article in the *Nation's Health* for March by Dr. Donald B. Armstrong, executive officer of the Community Health and Tuberculosis Demonstration, started in Framingham, January 1, 1917. Morbidity from tuberculosis has decreased fifty-five per cent. and the general death rate sixteen per cent.

* * *

In the *Atlantic Monthly* for April, George Arliss, the actor, writes on the psychology of play audiences. Another article of interest to the psychologist is the Behaviorism of Our Grandmothers, by Elizabeth A. Drew.

* * *

Two addresses delivered at the Public Health Exposition in New York City in January are reprinted in the *Monthly Bulletin of the Department of Health* for February. These are both entitled How Sanitation Aids Public Health, and are by Dr. Alonzo Blauvelt and by Richard P. Walsh, chief sanitary inspector.

* * *

The *Century* for April contains a number of unusually good articles and stories. Among these are the opening of a novel by Willa Cather, A Lost Lady; The Revolt of the New Immigrant, by Maurice G. Hindus, who believes that the attitude of the European peasant immigrant to this country is not the result of old world or alien influence, but the outcome of the long and painful process of socalled Americanization, which he is not ready to receive; The Ku Klux Klan, by Frank Tannenbaum; Women's Part in the New Rennaissance, by Lucie A. Zimmern; The English Lecturer in America, by S. K. Ratcliffe, who has himself been lecturing for several years before audiences of American intelligentsia, and Salvation by Jazz, by Carl Van Doren, editor of the magazine, who dubs the poet, Vachel Lindsay, an evangelist in verse.

* * *

Dr. Arnold Gesell, professor of child hygiene and director of the psychoclinic at Yale University, has an article on Feeblemindedness, State Policy and Control, in the *Nation's Health* for March. The solution proposed is proper vocational and supervisory methods.

* * *

A law in Chili requires factories employing fifty or more women to provide care in day nurseries for the children of the operatives.

* * *

In *Current History* for April, Prof. Roy Malcolm, of the University of Southern California, writes on the Problem of the American Born Japanese. Japanese children born in the United States he has found to be better physical specimens than those born in Japan, and to exhibit a special aptitude for study, and for adoption of American customs and standards.

* * *

The *World's Work* for April contains several articles dealing with interesting personalities. Among these are Some Encounters with Kings and Queens, by Sir Philip Gibbs; From the Home to the House, by the Viscountess Astor; and Paderewski, a Great Man, by Silas Bent.

* * *

The United States Public Health Service is conducting a study of rural malaria in Yazoo County, Miss., which has furnished such interesting data on the use of creosote oil as a mosquito repellant that a preliminary report has been published in *Public Health Reports* for March 9th. The writer is Dr. C. P. Coogle.

* * *

A legislative act passed in Denmark on July 10, 1922, contains provisions concerning the employment of children and young persons in handicraft and industrial transport undertakings. Among these provisions are that in industrial undertakings no children under fourteen shall be employed at all, and that no young persons under eighteen shall be employed at night work.

New Publications Received.

VITAL STATISTICS. By GEORGE CHANDLER WHIPPLE. New York: John Wiley & Sons, 1923.

PRACTICAL PHYSICS. By J. A. CROWTHER, Sc.D., F.Inst.P. London: Henry Frowde and Hodder & Stoughton, 1922.

CLINICAL LABORATORY METHODS. By RUSSELL LANDRAM HADEN, M.A., M.D. St. Louis: C. V. Mosby Co., 1923.

ORTHOPEDIC SURGERY. By SIR ROBERT JONES, K.B.E., C.B., and ROBERT W. LOVETT, M.D., F.A.C.S. New York: William Wood & Co., 1923.

MATERIA MEDICA FOR DENTISTS. By FRANK COLEMAN, M.C., L.R.C.P., M.R.C.S., L.D.S. Fifth Edition. London: Henry Frowde and Hodder & Stoughton, 1922.

A TEXTBOOK OF THE PRACTICE OF MEDICINE. By Various Authors. Edited by FREDERICK W. PRICE, M.D., F.R.S. London: Henry Frowde and Hodder & Stoughton, 1922.

Practical Therapeutics

MYRINGOTOMY IN THE TREATMENT OF ACUTE OTITIS MEDIA*

By M. S. Ittelson, M. D.,

Brooklyn.

There are acute cases of middle ear affection where surgical intervention is clearly indicated. Pus in the middle ear needs an incision in the drum. The accepted surgical principle *ubi pus, ibi evacua* holds good here as it does in other parts of the body. But in a fair proportion of cases presented for examination it is difficult to determine definitely that this condition is present. In these doubtful cases the question frequently arises whether to operate or to treat the patient expectantly. There is a difference of opinion on this point. It may be of some value to know the reasons for the different views.

The dissension in the treatment of acute otitis media is in a large measure due to the difficulty that is frequently encountered in the attempt to determine the nature and the extent of the inflammatory lesion that is present. A satisfactory examination of the ear is not always possible. It is difficult when the patient is restless; when the canal is narrow, or when the view of the drum is obstructed by hair, adherent epithelial shreds or other material the removal of which irritates the parts and alters the picture. Bulging of the drum, unless marked, may be difficult to recognize. Neither is this bulging an accurate indication as to the amount of pressure to which the drum is being subjected. A relaxed and thickened drum may sag or prolapse almost from its own weight. A tense drum, on the other hand, will resist much of this intratympanic pressure and will show little change although an extensive exudate is present. It is frequently difficult to determine whether the suspected fluid is serous, sanguineous or purulent, and it is upon this point that a choice of treatment sometimes depends. Neither can we judge the progress of the infection from the aural examination or whether the inflammatory process is advancing or receding. In either case the autoscopic picture may for a time remain unchanged.

The history and constitutional symptoms, including pain, temperature and general appearance, are exceedingly important, but there are times when the information that we get from this source is also meagre. Children cannot localize or indicate their pain. With an acute otitis media they may point to the abdomen or to another part of the body. Rolling the head and putting the hand to the ear are suggestive but often these symptoms have no significance. The amount of earache complained of depends on the temperament of the patient. A neurotic patient will exaggerate a pain while a phlegmatic individual will underestimate it. An elevation of temperature is generally present in otitis media, but this fever can be caused by many other conditions which may be difficult to exclude. The cases therefore are numerous, particularly when the otitis media occurs secondary to some other disease, where an early accurate diagnosis cannot readily be made.

In the treatment of these cases we have the uncertainty in the diagnosis on the one hand; on the other, the fear of complications which may result from a delay in incising the drum. It has been repeatedly emphasized that prompt surgical measures are the most effective ones that can be employed and that an early incision in the drum is an essential requisite for the prevention of the further spread of the inflammatory process. By this means an exit for any possible exudate is provided, and the patient is given the best chance to escape needless pain, chronic suppuration, mastoiditis, and other more serious consequences. It has also been emphasized that to wait for a spontaneous perforation is inexcusable, that the opening made by Nature is seldom sufficient to give adequate drainage, and that such perforation usually occurs too late to prevent serious complications. An incision properly performed is without risk and, if the inflammatory process is not severe, the drum membrane has a tendency to heal rapidly. With an early incision therefore there is much to gain and little to lose.

This is the rule which is generally recommended in the textbooks and one which is widely followed, yet there is a strong suspicion that this conclusion is not entirely correct. It may be of historical interest to know that paracentesis in the treatment of acute otitis media is a comparatively recent operation. Introduced by Schwartze in 1870, it was not until several years later that this procedure became of general use. Many careful observers, and among these must be included Zaufal and his followers, express grave doubt that the retention of a purulent exudate in the middle ear cavity is a causative factor in the production of mastoiditis. The occurrence of this, as well as other complications, in their opinion, is essentially due to the nature of the infection, the anatomical character of the temporal bone, and the resistance of the individual. They also believe that acute otitis media, particularly in children, frequently runs a definite, cyclic course, not unlike pneumonia. Beginning with a sudden onset, sometimes with a chill, the temperature and pain continue for seven or eight days, when a sudden change takes place and recovery frequently follows. They are therefore in favor of postponing surgical interference until such time and to employ it only in those cases where resolution does not take place.

There is evidence to support this latter opinion. Mastoiditis does follow an early and adequate incision of the drum. Evidence is lacking that after a late incision complications are relatively more frequent, or that they occur because of this delay. The course of the disease, where for some reason or other an operation is postponed, and where spontaneous perforation takes place, is frequently so favorable that there is little reason for regarding such an occurrence with apprehension. The relief of pain following myringotomy is limited to the cases where the pain is due to the pressure of fluid on the drum. Frequently in the early stages of this disease, an exudate is absent and the drum membrane is retracted. Under these circumstances the pain that is due to causes other than to this pressure unfortunately persists in spite of an incision. An objection to an early myringotomy is that it is more likely to be unnecessary; and this objection cannot be entirely disregarded. Obviously a discharging ear is avoided when the drum membrane is intact. It has been demonstrated that bacteria from the nasopharynx gain access to the middle ear more rapidly when an opening in the drum is present. Even by observing all aseptic precautions, a sterile cavity may be contaminated, or a different organism may be introduced and a mixed infection may follow. In a child already debilitated by disease, it may be particularly desirable to avoid or at least to postpone all surgical procedures except those urgently required.

---

*Read before the New Utrecht Medical Society, Brooklyn, N. Y., October 19, 1922.

It may be of interest, therefore, to know that recently a few physicians, both pediatriasts and otologists have accepted, perhaps independently, Zaufal's recommendation and have delayed myringotomy for several days in the treatment of acute otitis media. In the beginning of the disease, and this applies to the cases where the classical symptoms such as pain, temperature and a bulging drum are present, the patient after receiving a laxative is put to bed. A weak epinephrine solution is instilled into the nostrils to reduce the nasopharyngeal congestion. The customary glycerin ear drops are prescribed, and the ear is frequently irrigated with a hot solution. If after waiting four days the local and constitutional symptoms do not improve, an incision is then performed. The milder cases can thus be more easily eliminated. In the more severe cases it is asserted that there is an advantage if before incising the drum the inflammatory process is allowed to become somewhat localized and walled off, and the patient is given a chance to develop some immunity to the invading organism. The physicians who have followed this method report that the number of cases requiring myringotomy have been considerably lessened and in those cases where it had to be done mastoiditis as well as other complications have been relatively rare.

It is not my intention to accept as final the findings of one group of men as opposed to another group. It is important, however, that the different views should be more generally known. While the advantages of an early incision have been repeatedly emphasized, the contrary opinion until recently has been largely ignored. It is doubtful whether a physician has been given an accurate picture as to the probable outcome of the disease after conservative treatment. Possibly it is for this reason that in the recent influenza epidemic there has been according to Dench "a lack of discrimination in opening the membrane."

Myringotomy, like any other valuable operation, has its limitations. The danger of a delay can be unduly emphasized. Acute otitis media is a comparatively frequent condition. In any general disease affecting the upper air tract, an otitis is not unusual. A large number of these patients do get well whether the drum is incised or not. It would be highly desirable if surgical interference could be limited to those cases that really need it. The readiness with which this object can be attained is in direct proportion to the extent that these different views are clearly and dispassionately kept in mind.

Letters to the Editor.

SOAP THE EXCITING FACTOR IN DIFFUSE OTITIS EXTERNA (ECZEMA)

Philadelphia, *March* 20, 1923.

To the Editor:

For some years I have been impressed with the feeling that otologists frequently overlook the importance of soap as the exciting factor in many cases of eczema of the external auditory canal with the accompanying intolerable itching. That various types of external irritants are responsible for this troublesome condition is mentioned in the textbooks—even water is not overlooked; but the rôle of soap has not been mentioned in this particular type of the condition.

All patients who have been instructed to occlude the auditory canal with a well greased plug of cotton before washing the face and neck have reported relief from the itching or cure of a condition which formerly had resisted the usual treatment at the hands of other physicians. It is not intended to convey the idea that all other local or general treatment is thus rendered useless, but this procedure aids in hastening or effecting a cure.

Harry A. Schatz, M. D.

CANCER IN ANIMALS

San Francisco, Calif., *March* 27, 1923.

To the Editor:

An editorial entitled Cancer in Domestic Animals, published in the March 21st issue of the New York Medical Journal, reminds me of personal observations along that line.

Cancer of the clitoris, beginning as a small epithelioma, is common in the mare. Rarely it becomes carcinomatous and slowly progressive, involving the whole pelvic region. Veterinarians can remove quite a large growth involving the external genitals and healing will be so perfect that the mare may be disposed of in the market with but little question of her soundness, before the deeper metastatic processes manifest recurrence. I personally know of one such case. Two other mares in the same stable had epithelioma of the clitoris which remained dormant and never caused trouble.

Melanotic sarcoma is common in the mare and infrequent in the male horse. It occurs primarily as multitudes of smooth peasized nodules on the under surface of the stub of the tail from whence it spreads to the perineal tract in the form of granular excrescences and may remain so for years. Rarely it extends to the whole after half of the animal, appearing externally and internally.

Some years ago I removed a mass as large as a baseball from a mare's hip and had the mass sectioned in a laboratory. This mare had thousands of nodules over the whole after half of her anatomy.

My attention was called to this disease by Dr. W. E. Wadams, a veterinary surgeon of Santa Clara, Cal.

Ethan H. Smith.

Abstracts from Current Literature

SURGERY.

Surgical Treatment of Chronic Ulcer of the Body of the Stomach.—William Billington (*British Medical Journal,* July 8, 1922) asserts that he has seen poor results following surgical procedures in gastric ulcers, regardless of the technic employed. The chief determining factor for success is the situation of the ulcer: the further the ulcer is from the pylorus, the more difficult the relief of symptoms and the less satisfactory the results, regardless of the pathology of the ulcer. Röntgenography shows that an ulcer of the stomach produces a spasm of the segment in which the ulcer is located, a considerable delay in the passage of the gastric contents past the ulcer and feebleness or absence of peristalsis in the rest of the stomach. Success in relieving the symptoms depends upon the relationship between the site of the ulcer and that of the new stoma: the latter should be placed well on the proximal side of the ulcer and the ulcer and the stoma should have a definite relationship to each other. To secure proper drainage of the stomach and to avoid the formation of the distal pouch, a second anastomosis between the distal pouch and the jejunum should be made, or the pouch should be exterminated.

Chronic ulcer of the body of the stomach should be treated as though an hourglass constriction existed at the site of the ulcer, either with a partial gastrectomy, the distal pouch together with the ulcer being removed and the proximal pouch anastomosed to the jejunum, or with a double gastroenterostomy, with openings between the stomach and jejunum on either side of the ulcer. The choice between these two procedures is determined by the conditions found at operation and the clinical evidence of malignancy. The latter procedure is preferable, either with a single long opening or with two separate anastomoses. The results are excellent. The question of malignancy must also be considered and this is determined by the duration and persistence of the symptoms. A short history with persistent and increasingly severe symptoms is highly suggestive and calls for gastrectomy, if possible. The ulcer should be excised or destroyed by the actual cautery, provided the stomach on either side is drained, but this is unnecessary in the simple cases and impracticable in the worst cases. The operation which is the least severe and gives just as good results as the severe operation should be selected.

Treatment of Dislocation of the Foot.—B. H. Moore (*Surgery, Gynecology, and Obstetrics,* December, 1922) states that primary reduction is most desirable and gives excellent results. The method of reduction depends on the variety of the dislocation, and utilizes the underlying principle of the reversal of the force causing the dislocation. Irreducibility is not infrequently a complication mentioned in the case reports in the literature. The causes given are: 1. Interposition of a portion of the annular ligament between the scaphoid and the head of the astragalus. 2. Engagement of the neck of the astragalus by the tendon of the anterior tibialis muscle or in extreme cases by the tendon of the posterior tibialis. Quénu lays stress on the first cause, while Baumgartner and Huguier emphasize the second. Either condition would call for open reduction.

For old dislocations, astragalectomy is the method of choice. Quénu advocates it for all over nine days old. This seems rather radical as the first case reported was not reduced until two weeks after the injury, and yet no great difficulty was encountered and the result was good. One case is reported in the literature in which closed reduction was accomplished six months after the injury. This was in the preantiseptic period and at the present time probably would have been operated on. Baumgartner and Huguier collected the results of twenty-three astragalectomies for old, irreducible, and compound subastragaloid dislocations. Of these, thirteen gave good function, six resulted in ankylosis, one required secondary amputation, and two resulted in death from sepsis. These cases included those operated on in the preantiseptic period. Since their report, Thienhaus and Quénu have each reported an old case treated by astragalectomy, with excellent results.

Subastragaloid dislocation of the foot is a rare injury, alternative with abduction and adduction fractures in the region of the ankle. The physical signs of subastragaloid dislocation outward are eversion and abduction of the foot, with prominence of the head of the astragalus on the inner side of the foot. In old cases there is lowering of the malleoli and thickening of the foot below the malleoli. Treatment in recent cases is reduction, either open or closed as may be indicated. Total astragalectomy gives good results in old cases.

A Method of Reducing Congenital Dislocation of the Hip.—F. W. Goyder (*British Medical Journal,* September 16, 1922) proposes the following method for the reduction of the left congenital dislocation of the hip: The patient's sacrum is placed on a sandbag and the right side of the pelvis is steadied by an assistant. The knee and hip are flexed, the latter as much as possible till the knee lies as close as possible beside the trunk. With the surgeon's right hand upon the patient's left knee, the aim should be: 1, to push the head of the femur toward the acetabulum by downward pressure, and, 2, to direct the movements of the femoral head by rotation at the knee. The palm of the surgeon's left hand is placed against the great trochanter with the thumb in front and the fingers on the neck of the femur behind. While downward pressure is maintained with the right hand to keep the femoral head as low as possible, an attempt is made, by lifting with the finger of the left hand and depressing the right hand with or without rotation, to put the head below the acetabulum. The forward position of the head is maintained while gradually relaxing the pressure on the knee, when the head sinks noiselessly into the acetabulum. External rotation at the hipjoint brings the limb into the Lorenz position. The thigh should finally be approximated at right angles to the body and the knee should be more dorsally flexed than the pubic symphysis, so that the head of the femur is fairly prominent in the groin.

Forward Dislocations of Both Bones of Forearm at the Elbow.—I. Cohn (*Surgery, Gynecology, and Obstetrics,* December, 1922) states that anterior dislocations of both bones of the forearm are rare. In all cases which have been verified by operation or autopsy, there has been an extensive laceration of the ligaments about the joint and a stripping up of the muscles in the immediate vicinity from the respective bones. Anterior dislocations of the elbow may be either uncomplicated, or associated with a fracture of the olecranon or coronoid process. A review of the literature suggests that some of the cases have been reduced with very little difficulty. In the case which formed the basis of the author's report there was an extensive stripping up of muscles and interposition of soft parts between the lower end of the humerus and the ulna. Such a condition indicated the impossibility of a nonoperative reduction, particularly if seen late. The approach to the elbow in such instances had best be done by lateral incisions rather than the linear posterior incision, or the method recently suggested by MacAusland. The position after operation had best be one of complete extension, because the olecranon in complete extension is fixed in the olecranon fossa behind the trochlea. If the elbow is put in hyperflexion there is a tendency of the olecranon to slip forward again and reproduce deformity. After a few days it is advisable to begin mobilization of the joint.

Fracture Dislocations of the Humeral Head.—Weller Van Hook (*Boston Medical and Surgical Journal,* December 28, 1922) makes the following points: 1. Where wounds of the bony surfaces of any joint or of its capsule have occurred, and especially where loss of substance has taken place, fatty tissue (usually subcutaneous areolar tissue) should be implanted to cover the defect, whether or not the injured tissue lies between articulating surfaces.

2. Since transplanted fat tissue must become vascularized before it can be permanently stable in its new histological and functional relations, pedicled flaps are better than free flaps which must acquire entirely new blood and lymph vascular associations.

3. The removal of fragments of the humeral head, after simple fracture, gives excellent results under aseptic healing. But muscular attachments must be reestablished, capsular rents and bone surfaces deprived of endothelium should be covered with transplanted fascia and fat, dressing should be maintained in full abduction, and massage and passive motion must be instituted and kept up until the maximum of function is restored.

Reconstructive Surgery.—G. R. Girdlestone (*Practitioner,* December, 1922) says that the qualities most needed in this work are: 1, A capacity for thorough and careful examination of the case and its history with special inquiry into the actual disability of function and how far that interferes with the patient's wage earning capacity and vitality; 2, the power of recognizing what are the essential points of the disability, though perhaps they are not the most obvious ones; 3, an ability to assess at their real value the probable end results of the various methods of treatment, as judged by the patient's ultimate health, activity, freedom from pain, and fitness for work.

Cholecystectomy. — A. J. Brown (*Surgery, Gynecology, and Obstetrics,* October, 1922) asserts that the functions of stomach, duodenum, and pancreas are very closely connected by the sympathetic nervous system. A break in this system made by an operation will cause a lack of coordination in the interaction of these various viscera which will give rise to disturbed digestion with resulting symptoms. This disturbance can be avoided by carefully performed intraperitoneal dissection of the biliary system with as little trauma and destruction of tissue as possible. In order that after operation the bile may have a free passage from the liver to the intestine, it is important that the normal relation between the stump of the cystic duct and the hepatic ducts be maintained. This can be done by anchoring the stump of the cystic duct in the incision made in the anterior leaf of the gastrohepatic omentum. Postoperative adhesions can be minimized by forming cuffs of the peritoneum covering the gallbladder and after removal of the gallbladder, suturing the cut edges of these cuffs.

Experimental Cholecystenterostomy.—Gatewood and Poppens (*Surgery, Gynecology, and Obstetrics,* October, 1922) state that from experiments performed upon dogs in which the gallbladder was anastomosed to the stomach, duodenum, and colon, the following conclusions may be drawn: 1. The gallbladder invariably becomes infected regardless of the viscus used for anastomosis. 2. There is little, if any, difference between the stomach and duodenum in the matter of rapidity of infection. 3. The colon is not the portion of the gastrointestinal tract to be chosen by preference. The immediate dangers of peritonitis are much greater, and probably liver infections would occur earlier than when the upper part of the gut is used. 4. All livers become infected sooner or later if the method employed in our experiments be followed. 5. Cholecystenterostomy, from an experimental viewpoint, is not an operation to be recommended for use except in well selected cases, such as carcinoma of the pancreas where the temporary comfort of the patient is paramount, or irreparable common duct obstruction.

Pin Traction in Fractures of Forearm.——William H. Bailey (*Southern Medical Journal,* May, 1922) comes to the following conclusions: The glucose tolerance test has been shown to be of considerable assistance in establishing the diagnosis of cancer, especially of gastrointestinal carcinoma when the other conditions that give a similar blood sugar curve have been eliminated. Ether should not be the anesthetic of choice when the patient is found to show an acidosis by a low carbon dioxide combining power of his blood plasma, or some other of the accepted methods. In gastrointestinal cases showing a starvation acidosis a two stage operation may well be considered. A poorly functioning organ is to be feared more as a factor bearing on the operative risk of the patient than a diseased organ that is doing its work satisfactorily. Many deficient metabolic processes of the body may ultimately affect the functional ability of the kidneys. No one test for kidney function should be used to the exclusion of all others. Blood tests, like all other laboratory procedures, must be considered only as additional clinical evidence and their value determined by weighing them with all the data available. A phenolsulphonephthalein output of over seventy-five per cent. in two hours may be a sign of lessened kidney function. A low phenolsulphonephthalein result is not always an indication of a serious kidney impairment, especially when the blood retention products are not found to be excessively high. A high blood urea content is probably always an indication of lessened kidney function regardless of the results of the other tests. Satisfactory results cannot be expected from these tests if their performance be left to some one not thoroughly conversant with the chemical procedures involved. The estimation of blood creatinin is the most valuable prognostic sign we have in cases of renal deficiency.

The slight delay caused by these preoperative studies of the patient would not be a detrimental factor in lessening the patient's chances for recovery in the majority of operative cases. Blood chemistry is of special value in cases of hypertrophied prostate and other mechanical chronic obstruction to the outflow of urine. We should strive to attain that ideal, when every operative patient will be carefully studied by clinical and laboratory methods to accurately ascertain his "surgical risk" before operation, as then that epoch of physiological surgery will become an established fact.

GENITOURINARY DISEASES.

Erythrocyte Sedimentation Test in Urology.—Walter Pewny (*Wiener klinische Wochenschrift*, July 27, 1922) tested the rapidity of the sedimentation of erythrocytes in a large series of urological cases. As a rule, the test is positive in urethritis only in the presence of a simultaneous marked prostatitis, cystitis, or epididymitis. He believes it to be of value in the differential diagnosis in the following conditions: adenoma and carcinoma of the prostate, renal stone and renal tumor, etc. In this test, only the normal rapidity of the sedimentation should be considered. This test is also positive in infiltrative tuberculosis, neoplasms and in florid pyelitis in tuberculosis of the kidney and the bladder it runs parallel with the severity of the process, for which it may serve as a measure. During the course of the treatment it is believed to be an index of the success of the therapy.

Retention of Urine in Elderly Men.—J. Swift Joly (*Lancet*, July 22, 1922) says that the senile enlargement of the prostate is the most common causes of retention of the urine in men over sixty years old. The presence of residual urine is the first evidence of retention and the symptoms vary according to the amount of the residual urine. With a small amount, the symptoms are increased frequency of micturition, a diminution of the urinary stream and a diminished force and a delay in commencing the act of urination. With a large amount of residual urine, the symptoms are marked frequency, especially at night, a dribbling stream, without force and a marked delay in the starting, associated with straining; there is also polyuria and a diminution in the urinary solids and urea. The back pressure on the kidneys produces renal failure. The next stage is complete and chronic retention with overflow incontinence, renal failure and uremia.

In acute retention, if the bladder rises no more than two inches above the pubis, the bladder may be completely emptied by catheterization, hexamethylenamin is administered and the catheterization may be repeated in six to eight hours; bed rest is essential until spontaneous micturition occurs. If the bladder is overdistended, only fifteen ounces of urine should be drawn off at first; subsequently the bladder may be emptied either by catheterization every six or eight hours, gradually increasing the amount drawn off until the bladder is completely emptied, or a retention catheter, armed with a spigot, is introduced and four to five ounces are drawn off every hour. When once the bladder is emptied, it should not be allowed to refill. Patients with chronic retention and overflow incontinence, must be put to bed before any instrumentation is begun. A catheter is then passed into the bladder and the amount drawn off is determined by the average amount of urine which collects during one hour; this amount is drawn off through a spigot so as to avoid hematuria and suppression of urine. Catheter life should not be encouraged.

A New Method of Testing Kidney Function (Thiosulphate Test).—In view of the fact that none of the various tests for kidney function used heretofore have been found to be entirely satisfactory, W. Nyiri (*Wiener klinische Wochenschrift*, June 29, 1922) advances a new test with sodium thiosulphate. When this chemical is injected intravenously, sixty to seventy per cent. of it is normally oxidized into sodium sulphate, the rest (thirty to forty per cent.) appearing in the urine as sodium thiosulphate. With a disturbed renal function, only small amounts of thiosulphate appear in the urine, amounting to one to twenty-three per cent., according to the severity of the lesion. The greatest part of the excretion both in normal and diseased kidneys takes place during the first hour after the intravenous injection, there being little excretion in the second hour and in the third hour only traces, if any at all are demonstrable in the urine. The quantitative estimation of the thiosulphate in the urine is made with iodometry; the substances in the urine that normally bind iodine must be previously removed with animal charcoal.

The test is made is follows: After the patient has completely emptied his bladder, ten c. c. of a sterile ten per cent. solution of pure sodium thiosulphate in distilled water is injected intravenously. The patient then empties his bladder at three successive hourly intervals. After determining the quantity passed in each specimen, about twenty c. c. of each specimen are mixed with about 0.5 gm. of well cleaned animal charcoal and filtered for three minutes. About ten c. c. of each clear filtrate are then mixed with some starch solution and titrated with an accurately made one tenth normal iodine solution until the blue coloration appears. The urine passed previous to the intravenous injection is treated similarly as a control; according to its concentration, it requires one to two drops of iodine solution (0.05 and 0.01 c. c.). In the calculation of the amount of iodine solution used, 0.1 c. c. is deducted in every portion of urine. The calculation is made as follows: One c. c. of tenth normal iodine solution is equivalent to 15.8 mg. sodium thiosulphate and therefore 15.8 multiplied by the number of cubic centimetres of iodine solution used (less the 0.1 c. c. mentioned) gives the amount of thiosulphate contained in ten c. c. of urine. By estimating this for the whole one hour specimen, the quantity of thiosulphate is figured.

It is very important that only the best chemically pure animal charcoal be used and this be washed for several days previous to its use and then dried in the water bath in order to secure reliable results. This test was tried out on sixty patients (120 examinations) in both normal and pathological cases and was found trustworthy. Some of the kidneys showed normal values of 25.3 to forty per cent. of function in contrast to 0.20 to 0.85 per cent. in kidney disease. The advantages of this test are: a painless and harmless injection, urination three times at hourly intervals, the test taking only five to ten minutes to carry out, and the simplicity of the technic.

The Diagnostic Significance of the Wildbolz Own Urine Reaction.—After trying the Wildbolz own urine test in four hundred cases, Ernst Stiefel (*Schweizerische medizinische Wochenschrift,* July 27, 1922) comes to the conclusion that the negative result most likely excludes the existence of an active tuberculosis, if the test is carried out with the original technic and provided the Mantaux tuberculin reaction with 1:10,000 solution is positive. A positive result, however, does not absolutely indicate the presence of an active tuberculosis: forty-one out of 143 cases (twenty-eight per cent.) showed a positive result without any clinical symptoms of active tuberculosis. It can well be imagined that the antigen may possibly be produced in purer solution through an improvement of the technic, so that false reactions may be prevented from occurring.

Interstitial Cells of the Testicle.—Carl Sternberg (*Wiener klinische Wochenschrift,* July 20, 1922) states that many of the more recent investigations (excluding the transplantation experiments) show that an endocrine effect on the external sexual characters through the interstitial cells has not been definitely proved and that, as a matter of fact, most of the findings militate against this assumption. He denies the existence of the puberty gland, and in so far as Steinach's rejuvenation procedure is based upon this assumption, it rests upon false premises. Nothing is said as to the practical value of this operation as that is left to those with experience in this particular field. It has been positively shown that the interstitial cells appear very early in the embryonal development, and most likely they represent variations of connective tissue cells. In certain stages of fetal life they are found in great numbers, to decrease in amount later; an increase of the same occurs about the time of puberty. Under pathological conditions, an increase of the interstitial cells is often found in atrophy of the testicle from the most varying causes, but by no means always. All of these findings support the theory of the interstitial cells being accessory organs of the generative parenhcyma of the testicle, even though many of the findings formerly established can be made to conform with this assumption only with much difficulty. Some of the findings suggest a resorptive or resorptive secretory activity, and frequently it appears as if the interstitial cells were merely a compensatory substitute proliferation for destroyed parenchyma of the testicle.

Rupture of Bladder.—T. T. Thomas (*Annals of Surgery,* July, 1922) says that intraperitoneal rupture of the urinary bladder is infrequent and its literature scanty. Its mortality is still high but has been much improved in the past forty years, before which recovery was almost unknown. The absence in the posterior or peritoneal wall of the normal bladder of a sufficient laxity for easy and secure suturing of a rent in it is entitled to more consideration than it has received. Free escape of urine into the peritoneal cavity through an intraperitoneal rupture, closed poorly by suture or not at all, will not necessarily lead to a fatal peritonitis. Free suprapubic drainage with the Murphy enteroclysis and the Fowler position may lead to recovery.

Tumors of Urethra.—School and Braasch (*Annals of Surgery,* August, 1922) summarizes as follows: Malignant tumors of the male urethra often develop following long standing urethral infections. Primary tumors are extremely rare both in the male and female. In the female they are generally located in the anterior urethra and tend to grow outward, away from the bladder. Most malignant tumors of the urethra are squamous cell growths. They are highly malignant but are well walled off by fibrous tissue and lymphocytic infiltrations. They tend to remain limited to the local condition and to the regional lymph glands and usually respond readily to radium treatment. Three cases of epithelioma of the female urethra and one of the male urethra are reported from the Mayo Clinic. Benign solid tumors are only rarely seen in the urethra. The majority of these belong to the group of fibromyomas.

Treatment of Bladder Cancer.—W. E. Lower (*Annals of Surgery,* September, 1922), speaking of end results in operations for bladder cancer, summarizes as follows: 1. A large percentage of the malignant cases are of papillary origin, which means that they were referred late to the surgeon. 2. The percentage of recurrence is great whatever the method of operation, whether excision or cauterization. 3. Recurrence is no contraindication for treatment, as some of the best results have resulted from operation on cases with recurrences. 4. Repeated observation after operation is absolutely essential if the mortality of carcinoma of the bladder is to be reduced. 5. The good results of the treatment of recurrences are due to the fact that recurrences are nearly always local and very seldom metastasize.

Effect of Radioactive Baths on the Wassermann Reaction.—Mittenzwey (*Wiener klinische Wochenschrift,* July 27, 1922) reports on the favorable influence of radioactive baths on the Wassermann reaction and on the clinical symptoms, namely, in tertiary syphilitic processes. In six cases the Wassermann reaction showed a distinct improvement. The clinical improvement is the result of a marked perfusion of the infiltrated tertiary lesions with blood, thereby favoring the action of antisyphilitic drugs. The old disease depots must first be loosened up by overheating to make them accessible to the blood and lymph circulations and to render mobilization possible. This may explain the cases that show clinical improvement after the administration of nonspecific remedies without any corresponding serological improvement.

DISEASES OF THE EYE AND EAR.

Significance of Retinal Hemorrhages.—C. O. Hawthorne (*British Medical Journal,* September 16, 1922) draws the following conclusions: 1. Retinal hemorrhages may exist without recognized prejudice to vision and ophthalmoscopic examination is therefore a necessary part of every clinical examination. 2. Such hemorrhages may be the first objective signs of serious disease. 3. The recognition of retinal hemorrhage is of great value in directing the observer to a correct interpretation of the clinical facts, while the prognostic significance of the observation *per se* is indeterminate. 4. Retinal hemorrhages occasionally exist as isolated clinical facts and when so existing are comparable to hemorrhages in other parts of the body (hematemesis, hematuria, hemophysis, etc.), for which there is no ready explanation at hand.

Recovery of Vision After Incipient Panophthalmitis Following Cataract Extraction.—H. Kirkpatrick (*British Medical Journal,* July 15, 1922) reports recovery of vision in an eye which was afflicted with early and virulent infection after an operation for senile cataract. The abortion of the panophthalmitis and the recovery of the eye are attributed largely to the thorough use of eye baths of magnesium sulphate. The action of such baths in gonorrheal ophthalmia is especially striking. This solution seems to exercise a powerful osmotic action through the inflamed membrane and its use is always followed by a very marked reduction in the chemosis and by the restoration of a healthy circulation in the conjunctiva. Excellent results are achieved in gonorrheal ophthalmia with this treatment in combination with urotropin and vaccines, provided the corneal ulceration has not yet advanced to the irreparable stage. The lotion should be applied thoroughly by using the eye bath with the patient in the reclining position and he should constantly open and close the eye so as to maintain the circulation of the solution. The application is made for at least five minutes and it should be repeated within two hours in severe cases.

Remote Results of Complete Homotransplantation of the Cornea.—Albert H. Ebeling and Anne Carrel (*Journal of Experimental Medicine,* November, 1921) performed the operation described on cats to develop a better technic for homoplastic transplantation. The technic consisted essentially in using a large rectangular flap, fitted like the door of a safe into the edges of the corneal opening, and in fixing it securely in its position by stitches. The following steps are described: The preparation of the eye, the preparation of the graft, resection of the cornea and transplantation; fixation of the graft, and postoperative treatment. A flap composed of the entire thickness of the cornea of a cat was transplanted to the cornea of another cat, and was found to be perfectly transparent two years after the operation. The curvatures of the cornea appeared to be normal.

Cataract Extraction with Iridotomy.—R. P. Ratnakar (*Indian Medical Gazette,* Setpember, 1922) describes two operations, one with peripheral iridotomy, the other with complete iridotomy. In the former operation he picks up the iris near the periphery with a pair of curved iris forceps, makes a vertical or radial slit in it two or three mm. long, then uses the cystotome and expresses the lens asin simple extraction. In the latter operation he picks up the iris at its pupillary margin, draws it out of the wound, and then with a pair of straight sharp scissors inserted into the pupil, one blade behind, the other in front of the upper margin of the pupil, makes a snip not up to the periphery. The advantages he claims for this method over extraction with iridectomy are: 1, little or no pain; no bleeding as the vessels are not cut across; smaller, neater and more regular coloboma. Just how a prolapse of the cut iris, which has once been drawn out of the wound, is to be avoided he does not state.

Therapeutic Use of Uveal Pigment in Sympathetic Ophthalmia.—Alan C. Woods and Arnold Knapp (*Archives of Ophthalmology,* November, 1922) report the case of a boy, eight years old, in which sympathetic ophthalmia followed an operation for a perforated corneal ulcer with prolapse of iris that occurred after gonorrheal ophthalmia. The inflammation pursued a steadily progressive course with all the symptoms of the severe type of sympathetic disease. All usual forms of treatment, diet, intestinal irrigations, pilocarpine sweats, mercurial inunctions, large doses of sodium salicylate, and nonspecific protein therapy, were without effect. The serum reaction to an antigen of uveal pigment was negative. The intradermal reaction to uveal pigment was strikingly positive, showing a marked hypersensitivity to pigment. The treatment with uveal pigment consisted of desensitization followed by active immunization, after which the serum reaction against uveal pigment became strongly positive. Synchronous with this, with one short period of acute exacerbation, the inflammation in the eye subsided, the eye became white and has so remained. The active process lasted for three months and has now been stationary three months. Vision is 6/60. The eye is free from inflammation, but shows peripheric retraction, adhesion of the iris, and capsular opacities. Tension is normal.

Mitral Stenosis*

By SIR JAMES BARR, C.B.E., D.L., M.D., LL.D., F.R.C.P., F.R.S.E.,
London,
Knight of Grace of the Order of the Hospital of St. John of Jerusalem in England.

Mitral stenosis has, perhaps, led to a greater amount of controversy than any other form of heart disease, and therefore affords scope for a much longer address than would be possible or advisable at present. I shall therefore content myself with some of the more debatable points in the clinical manifestations of the disease.

MURMUR IN MITRAL STENOSIS.

The characteristic murmur, when present, is so definite and distinct as to arrest attention at once and leave no doubt as to the nature of the lesion with which we have to deal. Even here opinions have diverged widely as to the phase in the cardiac cycle occupied by the murmur; some associating it with the auricular and others with the ventricular systole, while other murmurs are so long as to occupy the greater part of the ventricular diastole.

The significance of this murmur was first recognized by Fauvel and by him designated presystolic, but it was the late Sir William Gairdner who clearly depicted the clinical signs and the pathological importance of this disease, so that when the murmur, which he termed auricular systolic, or briefly the A. S. murmur, is present, the disease becomes one of the most easily recognized affections of the heart. On the firm foundation which Sir William Gairdner securely laid, a huge superstructure has been raised, much of which is of very doubtful value, and those who wish to get down to the bedrock of facts have much rubbish to clear away. It should be clearly understood that the disease can be readily diagnosed apart from any murmur, but the mere assertion that a patient has got mitral stenosis is of no value unless your diagnosis takes into account the nature and extent of the lesion and its effects. Often when the diagnosis of mitral stenosis has been made the lesion has passed into a more or less irremediable stage, so that our treatment can only be of a palliative character. More attention should be paid to the evolution of disease and its prevention than is common at the present day.

ETIOLOGY AND PATHOLOGY.

Of all the causes or exciting conditions of endocarditis and pericarditis, rheumatism holds the first place; the fibrous tissue seems to be specially vulnerable to the rheumatic poison, but the myocardium may be involved as well as the whole endocardium and pericardium in the inflammatory process. The valvular lesion is determined by the violent collision of the vulnerable valves, and this view of causation has a most important bearing on prevention and treatment, as, by relieving the labored action of the heart in the early stages of endocarditis, the mischief can be prevented or mitigated.

When the rheumatic poison, whether it be animate or inanimate, sets up endocarditis, the myocardium is, in the majority of instances, more or less involved. The systole of the ventricle is slow and labored to overcome the high intracardiac pressure which is set up by increased peripheral resistance. As compared with the temperature the pulse in these cases is not very frequent and may not exceed 90 even with a temperature of 103° F. The pulse is slow, full, and moderately strong, and the tension is well maintained. The blood pressure is much higher than it is in typhoid fever, pneumonia, or diphtheria. Among the earliest signs of endocarditis is a dull first sound and a delayed radial pulse, so that the former can be heard an appreciable interval before the latter is felt. By careful attention to these signs, endocarditis can usually be diagnosed some days before any murmur is heard. The much more frequent occurrence of valvular disease in the left heart than in the right is due to the much greater strain and more violent collision to which the valves are subjected. When the mitral valve is involved we get a beaded row of vegetations on the auricular surface of the valve about one quarter inch or three eighth inch from the margin where the cusps come into most violent apposition, and when the aortic valve is affected the damage occurs on the ventricular surface at the angle of the cusps, which are brought into forcible collision during their closure.

---

*Delivered before the Birkenhead Medical Society, February 9, 1923.

Copyright, 1923, by A. R. Elliott Publishing Company.

The vegetations arise from proliferation of the cellular elements in the subendothelial layer of the endocardium. These groups of cells burst through the endothelium, and fibrin is deposited on the rough surface. This has a most important bearing on treatment, for by keeping the blood pressure extremely low in rheumatic fever, endocarditis can often be prevented. Unfortunately the mischief has frequently occurred before we see the patient, and when the valve once has been damaged there is a tendency for the mischief to be maintained and developed, even under the ordinary action of the heart. It is much aggravated by violent collision of the cusps during palpitation, or from high intracardiac pressure from any cause, perhaps from the meddlesome interference of the physician with that much abused drug, digitalis. When free mitral regurgitation takes place, the blood pressure falls, and the pulse increases in frequency.

Children are prone to contract rheumatism, especially those with a hereditary tendency to the disease, but the joint affection may be so slight as to escape notice, and in many cases endocarditis is the only gross expression of the rheumatic affection. Following endocarditis, which may even not have been detected, mitral stenosis is not an infrequent sequence. Many writers have asserted that mitral stenosis is essentially a disease of early life, and some believe the disease to be frequently congenital. While not denying the occasional congenital origin of the lesion, I think it must be extremely rare, as the affection is very seldom detected under five years of age. Moreover, congenital disease usually affects the right side. It is very common in youth, but may occur at any age. Rheumatism is usually associated with, or follows, septic conditions of the throat and nose, and those children are specially liable who have no natural or acquired immunity. Up to the age of puberty the thyroid gland is often rather inactive, hence children are prone to adenoids and enlarged tonsils which prove a ready nidus for infective organism. I have long since pointed out that these conditions could be obviated by a recognition of the cause, giving children, when required, small doses of iodine and thyroid, and allowing a piece of solid iodine to volatilize in their dormitories.

When mitral stenosis has arisen from acute rheumatism the edges of the cusps which are principally affected become gradually united so that the funnel form of the lesion is eventually established. Frequently the cases begin with incompetence, pure and simple, but from fibrous contraction of the auriculoventricular orifice and agglutination of the edges of the valve segments arising from a far too liberal supply of lime, they finally end in stenosis either with or without regurgitation. In such cases you often get the buttonhole orifice.

Mitral stenosis is frequently associated with chorea, and here the mechanical determination of the disease is very apparent. It may arise in cases of protracted anemia associated with high blood pressure and frequent emotional excitement. But it does not arise in cases of exophthalmic goitre in spite of the violent palpitation, because the intracardiac pressure is not high and the lime salts, which are another determining factor, are deficient. It is not uncommon in chronic Bright's disease, and in these cases mechanical strain plays a most important part in its causation. In such cases the orifice is not usually much contracted, but the whole segments of the valve are much thickened, and may be atheromatous or contain calcareous nodules consisting of lime salts or sodium urate. The musculi papillares are much hypertrophied and the chordæ tendineæ thickened. The insertions of the chordæ tendineæ are spread out over the greater part of the cusps, so when there is long continued high intracardiac pressure the whole valve becomes very much thickened, and there is a great increase in the fibrous tissue, which eventually leads to puckering or contraction of the segments and the diaphragmatic or buttonhole variety is produced. Syphilis has also been set down as a cause, but if so, it must in my opinion, be a rare one. Dr. Byrom Bramwell thinks that in some cases large calcareous nodules in the walls of the ventricle—causing obstruction—are syphilitic gummata which have become calcified.

Mitral stenosis is more common in females than in males, for the simple reason that rheumatism and chorea occur more frequently in girls than in boys, and anemia and all emotional disturbances have a special predilection for the female sex. However, men are much more liable to this disease than is generally supposed; and in fact, the disease is much more common among both sexes than is usually recognized. This frequently arises from the fact that it is often overlooked when associated with mitral regurgitation. When associated with tricuspid stenosis I have seen as many cases of the double lesion in men as I have in females. Mitral stenosis is frequently associated with pericardial adhesions, and this arises from the fact that pericarditis is almost as common as endocarditis in children.

The disease is, as a rule, slowly progressive, and although sooner or later it leads to the death of the patient, yet, under proper care and treatment it is slow in its progress, and is quite compatible with a fairly long existence. I have known many cases of mitral stenosis of twenty to thirty years' standing.

In mitral stenosis occurring in early life the orifice usually assumes the funnel form. This arises from the fact that these cases are generally of rheumatic or choreic origin, and the margins of the cusps are primarily affected. The relatively high intracardiac pressure and violent collision of the cusps cause their edges to get cemented gradually together, and taper down into the ventricle as a hollow cone. In the experience of Sansom, Hilton, Fagge, and Hayden, the buttonhole variety almost replaces the funnel form in the adult, but this scarcely accords with my experience. I have found that while the buttonhole variety is scarcely known in children, it is not much more common in the adult than the funnel form. It is true that the orifice at the end of the funnel is often a slit, but that scarcely constitutes a different variety. The characters of the orifice and valve depend, perhaps, more on the age of the lesion than on the age of the patient, and also on the causes which gave rise to the disease.

If there be much fibroid thickening of the whole valve and of the auriculoventricular ring, or if there be much atheromatous degeneration with calcareous deposit, then more or less puckering is produced, and the orifice assumes the buttonhole variety. These conditions occur more readily in adults, and in them the lesion is frequently of long standing. In some cases the mitral cusps are so thickened and contracted that they merely form a transverse septum with a narrow slit between the auricle and ventricle. In such cases the chordæ tendineæ are frequently thickened and matted together, and the musculi papillares are in such a fibroid condition, that it would seem impossible for a first sound to be generated by the mitral valve. This, however, is the exception and not the rule; even in cases in which the orifice is extremely small and its edges much thickened, the valve curtains are usually in a sufficiently vibratory condition for developing sound. The insertions of the chordæ tendineæ are spread over the greater part of the cusps, and the musculi papillares are usually hypertrophied so that tension is vigorously applied to the whole valve. If the musculi papillares be pulled it will often be found that the only part not rendered tense is the thickened fibrous ring. The relatively small quantity of blood in the left ventricle does not muffle the first sound, which is directly conducted to the chest walls through the chordæ tendineæ musculi papillares, and the part of the heart causing the impulse.

The small hypertrophied left ventricle, the thick musculi papillares, and the high intracardiac pressure produce a loud thumping or booming first sound unless the valve be so contracted as to form a septum. The character of the first sound at the apex affords valuable evidence as to the condition of the mitral cusps.

In the evolution of mitral stenosis any excess of calcium ions in the blood plays an important part. The socalled good healing flesh simply means that there is an excess of calcium cement in the blood and tissues. Under certain circumstances this may be beneficial, but whenever there is any tendency to sclerotic changes in the body, nature's attempts at repair are apt to be far in excess of the requirements. In the case of mitral stenosis these excessive calcium ions may be the determining factor in the production of the disease. They raise the blood pressure, increase the force of the cardiac contraction, give rise to hypertrophy of the musculi papillares, cause violent collision of the mitral cusps, increase the formation of the fibroid tissue, and gradually cement and unite the edges of the cusps together. I shall have more to say on this subject when we come to speak of prevention and treatment.

DIAGNOSIS.

When we hear at the mitral area a murmur immediately preceding the first sound, or even a murmur during the long pause, it is a very simple matter to recognize the fact that there is some obstruction to the flow of blood from the auricle to the ventricle, although such an observation cannot be properly called a diagnosis. We want to know the nature of the obstruction, the size of the orifice, and the effects on the circulation. Any observer can recognize a presystolic murmur, but it requires some training to interpret its significance. A great many men base their diagnosis of the lesion on the presence of the characteristic murmur, and as it is absent in a large number of cases, they thus fail to recognize the disease, even in the very extreme and most urgent cases.

In a large number of cases in which the murmur is well pronounced the interference of the physician is uncalled for; but in many cases in which the murmur is absent judicious treatment may be of vital importance. In many cases the only murmur heard is a mitral systolic, due to regurgitation. Now, in my opinion, the treatment of these two affections is in many respects essentially different, and the failure to recognize the underlying condition of mitral stenosis may be fraught with great danger to the patient.

The character of the murmur and of the first sound may help us to estimate the nature of the orifice and the condition of the cusps, but it is only by an examination of the pulse, and by a careful study of the effects of the obstruction, that we can arrive at the far more important calculation of the size of the orifice or the amount of obstruction.

Of all the signs of mitral stenosis, the murmur is the most obtrusive, and, therefore, has perhaps received undue attention, to the neglect of other more constant, and, to my mind, more important signs. The characters and varieties of the murmur have been so well studied and depicted by numerous writers, that very little new can be said on the subject, but, nevertheless, the intensity of the murmur prevents our passing it over in silence in a paper dealing with a lesion in which it plays such a prominent feature. There is, perhaps, no cardiac murmur about which such a conflict of opposing opinions has been waged. Even the very rhythm of the murmur has been disputed, but at last we have arrived at an almost unanimous opinion, that the murmur occurs prior to the systole of the ventricle. Sir William Gairdner happily designated it auricular systolic, which implies a theory as to causation as well as rhythm. There has been the objection to this name that the auricle is often so thin and dilated as to be incapable of any effective contraction, and the objectors substitute the theory of elastic recoil of the auricle, forgetting that under such circumstances there can be no recoil of the auricle, and under no circumstances can the auricle be compared to the aorta or to an overstretched india rubber ball. The atrium may be so thin and dilated as to be incapable of any forcible contraction, but it is very rare for this to happen with the auricular appendix, and the current induced by its contraction may be sufficient to give rise to a murmur. When the muscular contraction of the auricle is so weak as to be incapable of giving rise to a murmur through the narrow or roughened orifice, it is not an imaginary recoil which can do so. Under these conditions there is no murmur, or it occurs at an earlier period owing to the suction action of the ventricle. When you get a rough, rasping, lowpitched murmur immediately preceding the first sound, it must be due to the contraction of the auricle or of the auricular appendix, and is, therefore, auricular systolic. A small hypertrophied auricle gives a powerful and well sustained contraction.

A murmur may arise under any conditions which are capable of giving rise to a *fluide veine*—hence, it is not at all surprising that it does frequently arise before the auricular systole from the blood rushing through a narrow orifice during the active dilatation of the ventricle. The suction power of the ventricles is a matter of ancient history. It was maintained by Brown, Langrish, and afterwards by the illustrious Haller, but it was not until 1878 that the force was expressed in millimetres of mercury pressure by Goltz and Gaule.

The suction power of the ventricle is much aided by the high intrapulmonic blood pressure. Sir William Gairdner recognized and described the murmur as occurring at different periods, and even during the whole period between the second and first sounds.

These different varieties of murmur were named by the late Dr. Bristowe early diastolic, middiastolic, late diastolic, and entire diastolic. The late diastolic corresponds to the presystolic of Fauvel and the auricular systolic of Gairdner. The early diastolic may be purely mitral in origin; but I am convinced that it is often confounded with a short, soft, blowing, diastolic murmur, which not infrequently occurs in this disease at the moment of closure of the pulmonic valve, and which arises from regurgitation through the pulmonic orifice into the right ventricle owing to high pulmonic tension and dilatation of the pulmonary artery. This murmur is usually short, but I have known it to be prolonged well into the long pause and nearly up to the first sound. The occurrence of the early diastolic and middiastolic mitral murmurs depends on high intrapulmonic and auricular blood pressure, a narrow orifice, and the aspirating force of the left ventricle.

The size of the orifice and the nature of the valve segments will largely influence the character of the murmur, as it occurs at any part of the diastolic period.

At an early stage of mitral stenosis, when the further progress of the disease may be largely modified if not arrested, the characteristic murmur is usually absent, or there may be only a mitral systolic murmur. Again, the murmur may be absent in the late stage, when much can be done for the comfort of the patient, and when it is most important to diagnose between mitral stenosis and mitral incompetence. I think, therefore, we should endeavor to recognize the disease independently of any murmur.

ENLARGEMENT OF THE LEFT AURICLE.

One sign to which I attach considerable importance is an extension of the cardiac dullness in the direction of the left auricle. Under normal conditions a line drawn from the centre of the suprasternal notch to the nipple, or a point on the left fourth costal cartilage where the nipple should be, and which for convenience I call the suprasternomammillary line, should mark the outer and upper border of the heart. Any extension of the cardiac dullness beyond this line in the direction of the outer part of the infraclavicular region should raise a strong suspicion of mitral stenosis. This portion of the heart is usually well overlapped by lung, and so it requires very delicate percussion to elicit the extreme margin.

I may here premise that the whole deep cardiac area should be carefully mapped out; we want to know the size and position of the whole heart and of its individual parts. The anterior surface is to a greater or lesser extent overlapped by lung, and so in every case the percussion note of the deep cardiac area is only relatively dull; and in order to get the first shade of dullness, we should, in my opinion, percuss gently from without inwards. When possible I adopt the Albert Abrams method of making the patient stand on a grounded metallic plate facing due West, with the hands and feet well apart, and I have my pleximetric finger encircled with insulating tape. When you wish to bring out the slight dullness or impaired note of the lung in the early or hyperemic stage of pneumonia, then the vibrations of the chest walls should be stopped by the whole left hand laid firmly on the chest, and the middle finger percussed. In this way you avoid the confusion arising from the resonance of the vibrating chest walls, and you obtain the further information of the resistance to the stroke. In the case of the heart, however, it is not a question of resistance or even dullness, but of variation in the percussion note. It is a good exercise to percuss out the cardiac dullness in the cadaver and compare that with the actual area occupied by the heart.

The superficial cardiac dullness gives you some information about the position of the anterior margin of the left lung, but so far as the heart is concerned, it is of no practical value. The cardiac dullness is usually given much too small in standard textbooks; if you compare these pictures with the areas occupied by the heart in the postmortem room, and under the x rays, you will be greatly struck with the difference. Turn the lungs aside and you will find that the anterior surface of a normal heart is as large as many illustrations of extreme hypertrophy. In none of Sansom's plates of cases of mitral stenosis is there any extension of the cardiac dullness beyond what I have termed suprasterno- (or simply sterno-) mammillary line. This, I believe, is not because it was not there, but because it was not marked out. This careful differentiation of the cardiac dullness has yielded valuable results in my hands, and I hope that others will find it worthy of accurate observation. One authority on the heart, who does not believe in the possibility of accurately mapping out the deep cardiac dullness, says that when he sees anyone attempting to do so he inquires if the percussor is trying to map out the heart in systole or in diastole. No doubt this appears very smart to the authority in question, but he should learn that there is very little difference in the size and position of the heart between systole and diastole —when one part of the heart is emptying itself another part is filling, and the whole heart always occupies the same position in the mediastinum between the two lungs. The total size of the heart is much more affected by even quiet respiration than it is by its own systole or diastole. In Muller's or Valsalva's experiment the space occupied by the heart may be reduced by at least a half, but when you are percussing out the heart the respiration is quiet, and therefore it is a heart full of blood which you are mapping out. Not only is it possible to map out the deep cardiac dullness, by percussion, but, where the costal cartilages are fairly pliant, with a little practice you can palpate out their deep area with your eyes shut. The enlargement of the left auricle can be made out both by percussion and palpation, and is one of the commonest phenomena in obstructive mitral stenosis, but in some cases of associated mitral and tricuspid stenosis I have noted its absence. Here the comparatively small amount of blood passing through the narrow tricuspid orifice was carried on without causing great distention of the left auricle.

The pulmonic second sound is accentuated. The intensity of this sound at the pulmonic cartilage largely depends on the amount of lung intervening between the artery and the chest walls. Frequently the sound is heard better over the conus arteriosus or right ventricle. In a certain number of cases there is a short, soft, blowing diastolic murmur (to which I have before alluded) in the pulmonic area, due to slight regurgitation through the pulmonic orifice. This is especially likely to happen when the right ventricle is dilated and hypertrophied, and does not completely empty itself during systole. At the end of ventricular systole, the high tension in the pulmonic artery drives a certain amount of blood back through the closing valves into the unemptied ventricle or the pulmonary artery may be dilated, and the cusps not quite sufficient to close the orifice; in this case the regurgitation is freer and the murmur longer, so that it may occupy nearly the whole diastole. Some think this explanation of the murmur unwarranted, as the valve is usually found competent at the autopsy, but there is a remarkable difference between the pressure of one inch or two inches of water and the pulmonic tension in a case of mitral stenosis.

Doubling of the second sound of the heart is a common phenomenon in mitral stenosis. It is not by any means a pathognomonic sign, as some have supposed it to be, but merely an exaggerated expression of a normal doubling, which can be heard in almost every healthy heart at the end of inspiration or commencement of expiration, and like the normal doubling, the second element of the double sound is invariably pulmonic.

The duplication undoubtedly arises from asynchronous closure of the aortic and pulmonic semilunar valves, and this does not directly arise, as is often assumed, from variations in blood pressure in the aorta and pulmonary artery respectively, but is due to asynchronism at the completion of the left and right ventricular systoles; a relatively large quantity of blood in the ventricle, and heightened blood pressure in its artery, necessarily protract its systole, and so delay the recoil of its artery with closure of its valve.

In normal doubling and in cases of mitral stenosis the right ventricle is overloaded and the resistance in the pulmonic artery is increased, hence the right ventricular systole is protracted, and the closure of the pulmonic valve occurs appreciably after that of the aortic valve. Moreover, the muscle of the right heart more closely resembles involuntary muscular fibre than that of the left, and consequently its contraction is not so brisk, but for the same reason it is more easily stimulated to contract. Doubling of the second sound is an important fact, and its interpretation in any individual case is usually easy, if you will content yourself with the simple intelligible theory which I have enunciated. In many cases of mitral stenosis this phenomenon is absent where it might be expected to be present. This is especially likely to be the case where the right ventricle is failing, free tricuspid regurgitation taking place, or the ventricle not emptying itself during systole. Under such circumstances the right ventricular systole is not protracted beyond that of the left, and so there is no doubling. Its absence, therefore, may be of more grave significance than its presence. We should therefore not view it as a certain sign of mitral stenosis, nor fail to recognize that lesion when that sign is wanting.

The fact that the double second sound is frequently more marked over the right ventricle than at either the pulmonic or aortic cartilages has been urged against the theory of its asynchronous origin. But the site of the greatest intensity of the normal second sound is also variable—in at least fifty per cent. it is also loudest over the right ventricle. If the pulmonary artery is uncovered by lung, even the normal second sound appears accentuated, and the closure of the valve may be felt as a distinct snap, but a good padding of elastic lung tissue interferes very materially with the conduction of the cardiac sounds. The mitral first sound may be well conducted to the parietes through the impulse, even when the point of impact has been entirely formed by the right ventricle; but then the second sound occurring at the beginning of diastole is apt to be absent at this point owing to the impact of the dilated right ventricle not being well sustained against the chest wall. The facts of each individual case should be examined in the light of the conditions present, and not by the theoretical consideration of the examiner. The sound, whether single or double, is best heard at the point of the chest through which it is best conducted by some solid media. Frequently, with one bell of a differential stethoscope at the aortic and the other at the pulmonic cartilage, a double second sound can be heard when only a single sound is heard at either point.

A double first sound is not infrequent, in fact, it is a common event in mitral stenosis. It is not put down as a sign in our textbooks, nevertheless it is a fact. It is difficult to account for this, as it must have been heard hundreds of times by every experienced ausculator. The only explanation which I can offer of this want of recognition of a matter of daily occurrence is the fact that this doubling of the first sound in mitral stenosis is often accompanied by a rolling or tumbling action of the heart which renders the sounds very complex and difficult to analyze. When the heart is working steadily there may be slight dissociation of the tricuspid and mitral first sounds, which is appreciated by the ear, but there may not be complete separation of the two elements.

In these cases the right ventricle invariably initiates the contraction, and the tricuspid element comes first, but before it is completed the mitral element is heard. This *quasi* doubling, or in many cases true doubling, may be followed by a single or a double second sound. Frequently the right ventricle, which is better supplied with blood, gets so far ahead of the left that it starts contraction before the latter is half filled, and so you get a tumultuous or rolling action of the heart. There is a strong pulsation felt over the right ventricle, and this is accompanied by a loud, clear, tricuspid first sound; this wave of contraction is propagated to the left ventricle, and this is accompanied by a short, sharp, mitral first sound. If this occurs soon after the preceding effective left ventricular systole, when there is little blood in the left ventricle, the aortic semilunar valve may not be opened, and in this way you may have twice as many cardiac contractions as pulsations at the wrist. When there is some blood in the left ventricle the semilunar valves may be opened and you get an early abortive systole; you may even have five or six of these small systoles shown in a sphygmogram before the lever reaches the base line. What, then, is the cause of these small pulsations in the down stroke, inasmuch as the action of the heart (or, rather of its right side) may be so powerful as to shake the precordium? It is, in my opinion, undoubtedly due to the overloaded right heart trying to get rid of its extra charge of blood, and so acting in advance of the left. In the sphygmogram a strong, vigorous pulsation, starting from the base line, corresponds to a quiet, even synchronous systole of both ventricles; this may be followed by a tumultuous rolling and apparently forcible action of the heart, but the pulsation at the wrist may be barely perceptible to the fingers, and only recorded in the sphygmogram as an abortive systole, or, as it is nowadays called, an extrasystole. There may be one, two, three, four, five, or six of these extrasystoles before perfect synchronism between the two ventricles is restored, and then you get a full, complete systole, or, as it is frequently called now, a compensatory systole. If the cardiac sounds associated with this tumultuous rolling action of the heart and with each abortive pulsation are carefully analyzed, the following result will be obtained, and, for the sake of clearness of explanation, I shall at first discard the consideration of any murmur which may be present:

There will be heard a clear, short, sharp, but not loud, first sound (which I believe to be tricuspid in origin). This is quickly succeeded by a dull, low-toned, short sound (which I consider of mitral origin). Then, after a short but appreciable interval, there may be a dull, feeble sound (which I ascribe to the aortic valve), and this sound may be absent or coincident with a fourth sound, by which it is quickly followed. This last sound is the loud, accentuated pulmonic second sound.

All these phenomena are often heard over the right ventricle, close to the ventricular septum, or the double second sound may require to be analyzed at the aortic and pulmonic cartilages. In these cases, when there is an auricular systolic murmur, it is usually absent during the extrasystoles, or it may occur as a slight rumbling noise between the two elements of the double first sound. When there is a mitral systolic murmur, it invariably succeeds the second element, and, like the sound, is short and feeble, as it arises from the abortive contraction of a half filled ventricle.

The rolling action of the heart is felt over the right ventricle, but as the two ventricles again assume their synchronous action the impulse is transferred further to the left, and the first sound becomes loud, sharp, and clear, and banging, quite distinct from the short, sharp, clear sound previously associated with the tricuspid valve.

The absence of the auricular systolic murmur with the extrasystoles shows that the wave of contraction is not propagated from auricle to ventricle. In 1886 I advanced the view which I had long previously held that in these cases of abortive systoles the wave of contraction is not propagated from the left auricle, which in many cases is so dilated as scarcely to contract at all, but from the right to the left ventricle. In all obstructive cardiac lesions the effect tells backwards in the course of the circulation; therefore, in mitral stenosis the cavities chiefly affected are the left auricle and right ventricle, which tend to become hypertrophied and dilated. There is also engorgement of the right auricle, all of the viscera, and of the whole venous system. On the other hand, the left ventricle remains a comparatively small cavity, always provided that there is no aortic lesion nor any free mitral regurgitation, and consequently can only throw a small quantity of blood into the aorta at each systole. This small supply to the arterial system does not demand a great holding capacity, and so all the systemic arteries become contracted, and thus the arterial tree is diminished; the arteriolar contraction raises the arterial blood pressure so that the capillary velocity is increased and notwithstanding the venous engorgement you do not get edema.

We have thus high pressure in both circuits, but it is relatively greater in the pulmonic circuit in proportion as the obstruction is comparatively greater and the area smaller. Again we have a comparatively large right ventricle and a small left; the former contains more blood, and therefore tries to discharge more at each systole, but, of course, in a given time no more blood can pass through the right ventricle than that which leaves the left; therefore the extra effort of the right is used up in maintaining high pulmonic tension, which, with the aid of the left auricle, drives the blood forcibly through the narrowed mitral orifice during diastole. The high pulmonic pressure and overloading of the right ventricle often tends to prolong the contraction of the right ventricle beyond the short, sharp, and effective systole of the left, and thus we get asynchronism in the closure of the two arterial valves, with consequent doubling of the second sound. The large distended right ventricle does not completely empty itself during systole, and frequently the discharge is so slight that it is again quickly distended, and then initiates contraction, which is propagated to the left ventricle before it is full. This contraction may get so far ahead of the left ventricle that the systole of the latter may be induced before it contains much more blood than is sufficient to raise the aortic valve. Thus we may get one or more abortive pulsations in the down stroke. This goes on till the right ventricle has disposed of its superfluous charge of blood, and then the rhythm may become quite regular until it is again overdistended. This overdistention of the right side, with initiation of contraction in advance of the left in some cases takes place in a regular rhythm, so that we get the socalled pulsus bigeminus, trigeminus, etc.

On auscultation of the heart this asynchronism at the commencement of ventricular systole may be so slight that the mitral first sound becomes merged in that of the preceding tricuspid sound, and thus we only get a long first sound; or the asynchronism may be so great that we get a regular tumbling action of the heart, and there may be two first sounds with one or two second sounds for a carotid pulsation as I have explained before. This peculiar action is most easily observed when the cycles are infrequent.

The sequence of events may be briefly described as follows: Starting with a forcible contraction of the left ventricle, which is evidenced by a strong apex impulse, loud mitral first sound,, strong pulse, and well marked aortic second sound, this full discharge well fills the contracted arterial tree, keeps the arteries full between the beats, and produces a gradual down stroke in the sphygmogram. The contraction of the right ventricle which accompanies this complete systole of the left may only partially empty its distended cavity; its first and second sounds are synchronous with those of the left side, although less pronounced. The partially emptied right ventricle is quickly recharged, initiates contraction which is propagated to the left ventricle, while the latter is only partially filled. In this case the systole of the right ventricle is more powerful, its impulse stronger, and sounds louder than those of the left.. This may occur only as an occasional irregularity, or, on the other hand, the right systole may keep in advance of the left for several cardiac cycles, and you may have an equal number of beats, or socalled extrasystoles, recorded in the sphygmogram before the lever reaches the base line. What is felt in the pulse as an intermission, or an irregularity in force and rhythm, or is recorded in the sphygmogram as one or more abortive pulsations, is represented on ausculation by an irregular tumbling action of the heart, or a loud thump followed by one or more irregular rolling motions. When the mitral orifice is much contracted, you may have a tricuspid first sound, then a mitral first sound, followed by a single second sound; or this may be resolved into aortic and pulmonic elements, for one carotid pulsation. This peculiar rhythm of the heart, with corresponding irregularity of the pulse, is increased by the lime salts, by digitalis and caffeine, and is lessened by decalcifying agents, by nitroglycerine, and atropine. It is also relieved by such agents as lessen the venous engorgement.

Although this peculiar action is pronounced in mitral stenosis it is by no means limited to that disease. It may arise when the innervation and balance of blood pressure in the two sides of the heart are disturbed from any cause. It is frequently associated with dilatation of the right side of the heart, as occurs in emphysema, with fatty degeneration of the heart, and atheroma of the coronary arteries. It is not uncommon in the infiltrated or degenerated fatty hearts of elderly people affected with an acute blood poison, such as erysipelas, septicemia, or diphtheria. It may occur in gout, either active or latent, but as a rule in these cases there is usually a true intermission; the whole heart comes to a standstill for one cycle. In a case of Stokes-Adams disease, which I published in the *British Medical Journal* in 1906, when the patient took a deep breath and held his chest expanded the frequency of the contractions of the right side of the heart was increased, but after a couple of beats the left ventricle came to a standstill and an epileptic seizure was induced; this continued until the large intrapulmonary vascular cavity was repleted. In many cases the peculiar rhythm arises from the fact that the right side of the heart is usually more susceptible to stimuli than the left.

It is not sufficiently recognized that the heart is not a single organ, but two organs—each of which has got its own definite work to perform—linked together for mutual assistance in cases of stress or difficulty.

All parts of the heart can be excited to contraction by various stimuli, except during the refractory period; but the right auricle is the most sensitive part of the heart, and responds to stimuli for some hours after the rest of the heart has become quiescent in death. The two auricles are intimately linked together by a community of muscular fibre, and, although the wave of contraction may, and I presume usually does, commence in the right auricle, it is quickly propagated to the left, and consequently their contractions are simultaneous. When the auricles have driven a sufficient amount of blood into the ventricles to raise the diastolic pressure and stimulate contraction the ventricular systole begins, and it is rapidly propagated over both ventricles. The right ventricle is usually more sensitive than the left, or is better supplied with blood, for when you get doubling of the first sound the first element is almost invariably associated with the right ventricle. Although the right ventricle usually initiates ventricular contraction, it is often slower in completing its work than the more powerful left ventricle, because when you get doubling of the second sound the final element is frequently pulmonic. In Muller's experiment and in cases of pulsus paradoxus the systole of the left ventricle may be delayed or abolished for one or more beats, owing to defect in the diastolic tension. All parts of the heart act rhythmically; but even in perfect health the rhythm is constantly liable to considerable variations, which are readily detected if you will take the trouble to measure the various periods of activity and rest, not in fifths of a second, but in fiftieths or hundredths.

The length of ventricular systole depends on the amount of blood to be driven, the power of the ventricle to drive it, and the resistance in front. If, then, the commencement of systole depends on distention, and its length on very varying factors, it would be very strange if the two sides of the heart were incapable of acting to some extent independently. When the balance of blood pressure in the two sides of the heart is disturbed, it would be a very extraordinary provision in nature if one ventricle had to wait on the other, or prolong its contraction, not in accordance with the work it had to do, but in accordance with the necessity of its fellow. Although in mitral stenosis the right ventricle invariably initiates the contraction, yet in many other conditions the left ventricle acts in advance.

The myogenists tell us that the rhythmic function of the heart is started and maintained by a stimulus generated at the sinoauricular node, and somehow or other this stimulus travels through the auricles down the auriculoventricular bundle to the apex of the ventricles and the papillary muscles, and back again to the base of the ventricles.

What is the nature of this stimulus and how it is propagated God only knows, as the nearest approach to a definition which I have heard is that a *stimulus* is a *stimulus*. In this case it is not Scotch whiskey but just a stimulus to contraction.

Now there are any number of stimuli to contraction—electrical, mechanical, and thermal, but this peculiar stimulus, about which we hear so much, and know so little, defies analysis or definition. If it were called a vitamine any number of medical men would swallow the absurdity. As to its mode of propagation nothing definite is known except that it is supposed to travel along the auriculoventricular bundle, and at the Stannius bridge between the auricles and ventricles it moves very slowly, and like an old flint gun often misses fire. The muscle fibre in this neuromuscular bundle is quite different from the ordinary cardiac fibre and there is no evidence that it ever contracts, and if it does, its doubtful muscularity would point to its contraction being slower than even that of involuntary muscular fibre.

How then can it convey this unknown stimulus as quickly as even a slowly contracting auricle? Some years ago Head suggested, without adducing a tittle of evidence, that this bundle has a wave of contraction of its own, which wave is picked up and reinforced by the ordinary cardiac muscles. We have got a neuromuscular bundle of peculiar construction for which the myogenists seem to have found a use in carrying an imaginary stimulus over the heart—they seem to forget that it might be of use as a nervous as well as a muscular connection between the auricles and ventricles. However, the bundle does not seem to be always necessary for the propagation of a wave of contraction, as Engelmann has shown that when one end of a strip of cardiac muscle is stimulated to contract the other end may follow suit even when the intermediate portion of muscle is frozen.

There are various embellishments of this myogenic theory, such as positive and negative chronotropic, dromotropic, bathmotropic, and inotropic influences. This stimulus runs the risk of being more or less frequently blocked by disease and drugs—especially by that much abused drug, digitalis, so it has been necessary to assume that every healthy muscle cell of the heart has the power of producing a stimulus of its own which it constantly does, and this is as constantly used up with every contraction, so that after each systole the heart is bankrupt of stimulus.

The myogenists have been getting into some difficulties of late with the bundle because there have been cases of heart block where the bundle was afterwards found to be healthy, and cases of normal rhythm where the bundle was destroyed.

Stanley Kent came to the rescue in the *British Medical Journal* of July 18, 1914, with one or more bundles linking up the right auricle and right ventricle and the left auricle and left ventricle.

No doubt these bundles are extremely useful, otherwise they would not be where they are, and probably like the rest of the nervous mechanism of the heart may save that organ from many an unnecessary jar and strain, but how long their function may be misinterpreted it is difficult to say. From a therapeutic point of view, so far as I can see, this apparently learned jargon to which we are regularly subjected leads only to the grave. If the heart comes to a standstill in syncope or chloroform poisoning are you going to wait for the imaginary stimulus to start at the sinoauricular node? If you do there may be an eternal silence. The proper plan is to apply a real stimulus inside the right auricle and ventricle of a pressure of fifty to one hundred millimetres of mercury by hanging the patient up by the heels.

It seems to be forgotten that rhythmic action is the function of all muscle, even the skeletal muscles act rhythmically under certain conditions; witness an ankle or patellar clonus a pressure of six or seven atmospheres will make any voluntary muscle contract rhythmically, and they can be made to obey a certain rhythm by electrical stimuli. The involuntary muscular fibres possess the function or rhythmicity in an especial degree and the more closely the cardiac fibre approaches the unstriped variety of muscle the more highly does it possess the rhythmic quality. Hence the auricles are more irritable and contract more slowly than the ventricles, and the right side of the heart is more irritable than the left. I have seen the right auricle respond to mechanical stimuli hours after the rest of the heart had ceased to beat.

If the heart were actuated by a stimulus generated at the sinoauricular node, then under any given set of conditions the stimulus would be paid out with rhythmic regularity and the heart would work like a clock. Some of our myogenic friends are bold enough to say that such is the case, but those of us who deal in hundredths of a second and who are not content with such gross periods as a fifth of a second, know that such is not the case. Nature is much more accommodating than the postulates of your heart specialist; the heart is constantly adapting itself to the work which it has to perform.

It is pleasant to pass from the speculations of heart specialists to the sound work which was carried on at Cambridge by the late Ralph Mines. He showed how the cardiac contraction is dependent on a difference of electrical potential between the ions within and without the cells. In an experiment which I saw in his laboratory on cutting the calcium salts out of the nutritive fluid supplied to the isolated heart it was seen that the electrical variation preceded the contraction of both the auricle and ventricle, and whether the cause or not of the contraction it began the sequence of events and therefore could not be the result of the contraction. The effect of pressure in stimulating contraction is well exemplified in the isolated mammalian heart when it is supplied with nutritive fluid through the coronary arteries; there is a regular rhythmic contraction and in addition when the right ventricle gets filled with the return current it gives an extra contraction on its own account to expel the fluid.

Every muscle in the body is a miniature battery, and the efficient discharge of its function depends on the integrity of the cell and its electrical charge; these cells are arranged in series, and in the case of the heart linked up by the sympathetic nervous system, or, if you prefer, the bundle of His and its ramifications. In health these batteries work well, but in disease there are many breaks in the continuity of the series. So far as we know, the presence of free calcium ions in the blood and tissues is necessary for effective muscular contraction. The calcium ions diminish the irritability of the muscle fibre, but increase the force of its contraction.

The myogenic theory is very nice and plausible, and deserves to be true, but like a good many other theories, it has not been considered necessary to establish the truth of the premises; not one scintilla of evidence has ever been adduced to show that the muscle cells, or any node or set of cells, generate any stimulus which excites contraction, and there is no information as to the nature of the stimulus. I said in 1906, and I say still, that the socalled myogenic stimulus, or the production of a stimulus of contraction as a function of the cardiac muscle is, as far as I know, purely an inference, possibly a figment of the imagination which exists in the brains of certain writers rather than in the cardiac muscle. Of course there may be such a stimulus, but before believing in it I should like to know what it is. If it were a salt of potassium, or sodium, or calcium, or an alkaloid like strychnine, or some difference in electrical potential, we might form some conception of its nature and action. Regarding the propagation of the stimulus, there is no evidence, but it is assumed that it does travel and that often it is much delayed in its transmission along the bundle of His; often taking more than one fifth of a second to travel eighteen mm., according to Leonard Hill who states: "The rate of propagation of the contraction wave in the heart is so fast, reaching five metres a second or more, that, for all practical purposes, we may say that the contraction of the whole ventricle is synchronous."

(*To be concluded.*)

The Minimum Symptoms and Signs Necessary to Make a Diagnosis of Organic Heart Disease*

By W. S. THAYER, M. D., Hon. F. R. C. P. I.,
Baltimore.

At the outset one must respond to the question proposed for discussion in much the same manner as one is obliged, too often, to reply on the witness stand to the persistent inquiries of the zealous advocate: "That, sir, is a question which does not admit of a categorical answer."

We arrive at the conclusion that organic disease of the heart is or is not present in any given instance, only by the exercise of our judgment upon information gained by the use of our senses, aided by the employment of certain instruments of precision. My dear old teacher, Francis Minot, used meticulously to discriminate between the symptoms and the signs of disease. But signs—diagnostic signs of a disease? How very few there are! Human understanding is too fallible often to justify us in venturing upon absolute statements in matters of diagnosis, and everything, in the end, depends upon the individual human understanding. And in such matters as those which pertain to cardiac diagnosis and prognosis, intelligent understanding cannot be acquired in the classroom, in the library or in the assembly—it can be acquired only at the bedside.

With regard to just such questions as that which is proposed for discussion, a competent opinion in the given case can be formed only after personal study of the patient. Language, alas, even when best employed, is but a poor conveyor of visual, tactile and auditory impressions. And lucidity of language, which depends in the end on studied simplicity of expression, is acquired only when one has learned to love the beauties, and to respect the purity of his tongue. Such simplicity and lucidity of language is, alas, none too common among the doctors of today. One shudders to think how rare 'twould be in the future if some of those naïve enthusiasts, who occupy prominent positions before the public today were to prevail—those naïve enthusiasts who, periodically, for generations, have proposed the abandonment of most of those studies whose immediate utility is not apparent, in order that the youth may be led more directly along the path of least resistance to the career of his choice. I say naïve, for their ideas are not new, and because they forget or ignore that the mastery of one's tongue is vital to real success in most learned professions, and that this mastery is rarely acquired other than through familiarity with, and love of, the classics in one's own and other languages.

The master of his tongue may, in a few strong words or lines, excite in his hearers or readers vivid visual or auditory impressions. But they are impressions. In detail, the impression of no two hearers or readers will be the same. But in diagnosis and prognosis it is often the detail which no word can convey, that inclines the scales of judgment.

For upwards of fifteen years, Dr. MacCallum or Dr. Winternitz and I have given an exercise in which we consider the histories of those patients who have died during the week. The history is given in summary and the impressions of the clinician formed without knowledge of the results of the necropsy, are written and read so that there may be no escape. Dr. MacCallum then shows the pathological specimens and speaks of the revelations of the necropsy. In such exercises, one learns soon that the value of his conclusions concerning an instance of cardiac disease which he has not seen himself, is exceedingly small. No description by another can picture exactly the conditions which have existed. It is obvious that in a discussion such as the present, one can speak on broad lines only, can touch upon certain points, and in the end perhaps, insist on the dangers and difficulties of arriving at a diagnosis rather than seek to establish any definite or absolute rules. I shall accordingly restrict my remarks to the consideration of a few circumstances under which a diagnosis of probable organic disease of the heart may be made upon evidence simple and unassociated with that corroborative testimony upon which we must generally rely.

---

*Remarks made in the discussion at the New York Academy of Medicine, December, 1921.

It goes without saying that an accurate history is of the greatest value in assisting us to arrive at proper diagnostic conclusions. Not infrequently where the physical manifestations do not justify a diagnosis in themselves, accurate information as to the patient's past history changes a suspicion to a strong probability—in other words, establishes our diagnosis.

There are conditions under which a diagnosis may be made without obvious cardiac abnormalities on physical examination and where a positive diagnosis of cardiac disease may be made from the history alone.

ANGINA PECTORIS.

Few would deny that a reasonably certain diagnosis of angina may be made from the story of the patient in some instances where there are no physical signs to support the suspicion. Such a diagnosis may justly be made in cases from the character of the pain alone even though its distribution be sometimes most unusual. Let me mention two instances.

Case I.—A man aged seventy-three consulted me with the following complaint: Upon walking up the hill which led to his house, he had, some days previously, been seized by a rather sharp, sickening pain directly between his shoulders; he found himself obliged to stop; so soon as he stopped, the pain disappeared but recurred again if he walked fast. This pain recurred under similar conditions and had become so annoying that he sought advice. Physically the examination showed soft peripheral vessels and a heart of average size with no demonstrable abnormalities; the blood pressure seemed a little high. But the diagnosis was clear. The attacks became more frequent and characteristic and, several years later, he died suddenly, almost without a movement.

Case II.—A man of sixty-eight, three months before consulting me, found that when walking fast he had a pain in the back of his throat. Later this became localized in the upper and lower canine teeth on the right side. He never had this pain until he had walked several squares; it disappeared when he stopped; the same sensation occurred if he went upstairs fast; in the bath tub he felt it when he rose; in other ways, he felt quite well. He was a large man; the measurements of the heart (percussion), though rather large, were not above the normal; the sounds were clear; the maximal blood pressure about 160. Both of the teeth referred to were devitalized. The note on my history card ends with these words: "The infallible relation of the attacks to exertion, the circumstance that he obtains relief the moment he stands still, and that he feels obliged to do this so soon as the pains begin, together with the rather high blood pressure, seem to me to indicate that the attacks are anginal in character." Gradually the attacks became more frequent and a year or two later the patient died suddenly.

There was no necropsy in either of these cases, and it is realized that the question may be raised as to the existence of cardiac disease—that one may ask whether the changes may not have been aortic alone. I admit the possibility, but my own experience has been that typical angina is rare in the absence of cardiac disease.

ENDOCARDITIS IN CHOREA.

Our observations have led us to feel that the diagnosis of acute endocarditis or myocarditis may be made with considerable probability in instances of chorea, where there is a febrile movement of any considerable extent. In an analysis of 808 cases of chorea, 107 were treated in the wards of the hospital. In thirty-five of these, where the temperature rose to 101° F. or above, thirty-one or nearly ninety per cent. showed evidence of valvular insufficiency or stenosis before leaving the hospital or on subsequent examination. If chorea be associated with well marked fever and no definite cause for this fever be apparent, it would appear to be fair to conclude that there is an acute cardiac involvement—endocarditis or myocarditis. It is obvious that unless myocardial lesions sufficient to produce a relaxation of the mitral orifice be present, the early stages of a socalled rheumatic mitral endocarditis could scarcely produce recognizable, localizing symptoms. A soft systolic murmur over the precordium in a child with chorea is no more diagnostic of endocarditis than similar manifestations in a child, healthy or affected by any other febrile disease such as typhoid. The existence of the endocarditis of chorea is commonly discovered only weeks or months after its onset, when sclerotic changes have set in in the affected valve. The small acute verrucosities of the valve can hardly themselves produce appreciable symptoms.

ADAMS-STOKES SYNDROME.

The characteristic Adams-Stokes syndrome with prolonged conduction time justifies the diagnosis of organic cardiac disease, even in the absence of demonstrable physical changes in the heart.

ELECTROCARDIOGRAPHIC EXAMINATION.

It would probably be fair to say that electrocardiographic examination reveals sometimes the only evidence justifying a diagnosis of organic cardiac disease—such as a persistent notching in all leads or evidence of bundle branch block, but these changes are, after all, rarely seen in the absence of other suggestive symptoms.

ARRHYTHMIAS.

Certain arrhythmias—notably persistent fibrillation of the auricles—would probably be regarded by most physicians as evidence of organic cardiac change even though that change be not demonstrable by other clinical signs.

There are conditions in which a murmur alone justifies a diagnosis of organic disease of the heart. So much has been said, and so justly said, anent the misinterpretation of cardiac murmurs and especially systolic murmurs—so much has been said as to the common errors in attempting to estimate the character and extent of the cardiac lesion from the character of the murmur, that it may not be amiss to assert here what is undoubtedly true—that in a given case the only evidence of organic cardiac disease may be the murmur heard, and that not very infrequently one is quite justified in making the diagnosis of organic cardiac disease on the presence of a murmur without other evidence.

AORTIC INSUFFICIENCY.

This is especially true in aortic insufficiency. The murmur of aortic insufficiency is very rarely heard outside of true valvular disease. Only once or twice in my work have I seen instances which appeared to be transient and due to a relaxation of the ring; once in exophthalmic goitre, and twice after typhoid fever. But instances like the following are not uncommon:

Case III.—E. L., aged thirty, consulted me in 1900. He was an athlete, and had been accustomed to taking violent physical exercise. There was no history of serious infectious disease. Two years before he had been told by a physician that he had a slight cardiac murmur and was refused insurance. He thought that on violent exercise he was a little shorter of breath than he used to be.

He was a healthy looking man; the heart was not enlarged; the impulse was under the fifth rib about eight cm. from the median line; there was no enlargement to the right; the sounds were clear at the apex, except for a loud inspiratory, cardiorespiratory systolic murmur; the second sounds were of normal relative intensity; on attentive auscultation, a soft to and fro murmur was audible in the third left space near the sternum; the diastolic murmur was faintly heard in the aortic area and along the left sternal margin with diminishing intensity. My notes read, "There is nothing in the pulse suggestive of aortic insufficiency, though the nature of the murmur would leave little doubt that it is an instance of aortic insufficiency." Five years later, the apex was in the mammillary line, 9.1 cm. from the median line signs as before. I saw this man again less than a week ago. He had remained perfectly well; had ridden to the hounds all his life and led a normal existence. But the heart was a little larger, the systolic murmur at the base had grown harsher; the pulse was smaller and of longer duration and suggestive of a definite aortic stenosis.

Here was a man in whom there was undoubted aortic insufficiency of so slight a degree as to produce little or no cardiac embarrassment. At the moment and through nearly twenty years of life, following, the lesion was revealed only by the presence of a murmur.

MITRAL INSUFFICIENCY.

No man with considerable experience in diseases of the heart can doubt that there may be instances in which mitral insufficiency of organic character may be recognized by the presence of a murmur alone. There are those occasional instances where a slight sclerosis of the valves with insufficiency so slight as to cause no subjective symptoms or no objective evidence of cardiac hypertrophy, are revealed only by the presence of a murmur associated with or replacing the first sound at the apex—a murmur of a character distinctly harsher and louder and perhaps longer than one ever hears in a heart of normal size in the absence of actual valvular insufficiency. An example of this is the following:

Case IV.—E. C., a girl of seventeen, was seen with Dr. I. E. Atkinson in consultation, May 22, 1902. The patient complained of obscure abdominal symptoms, suggesting peritonitis, coming on in the course of an unaccountable fever of about a week's duration. The heart was of normal size. There was a loud, long, blowing systolic murmur heard at the apex and through the back. The second sounds at the base were of normal relative intensity for a girl of her age. Two days later the patient died with symptoms of peritonitis. The necropsy showed a perforated typhoid ulcer. The heart was essentially normal in size with slight sclerosis of the mitral leaflets, and thickening and shortening of the chordæ tendineæ.

Now the diagnosis in this instance was rather simple, owing to the circumstance that two years previously, the patient had had a severe acute rheumatic fever with endocarditis. But it would have been equally clear without it, for the character of the murmur was such as could not have been present other than in organic mitral insufficiency.

In such cases as this, however, the element of personal judgment enters in, and it would be really impossible to attempt to explain to a class of students or to lay down a rule as to when a mitral murmur reaches such a degree of intensity or harshness or duration as to justify a positive diagnosis of disease of the valves. That there are murmurs as to the organic nature of which there can be little or no question in the absence of signs of cardiac enlargement or functional derangement, there is, however, no doubt.

MITRAL STENOSIS.

There is another phenomenon relating to the heart sounds, which in many instances justifies one in diagnosticating a valvular lesion. I refer to the mitral diastolic murmurs—the characteristic, rumbling, vibratory murmurs often associated with a palpable thrill, felt at and just within the apex in mitral stenosis—the murmur most unfortunately, I think, referred to in English and French literature as the "presystolic" murmur of mitral stenosis. These murmurs are presystolic often only in that they extend up to the first sound. They begin generally at an early period in diastole, namely, at the time of the third sound, i. e., at the moment of relaxation of the ventricle, and reach their maximal intensity shortly after this. If the pulse be slow, they commonly diminish in intensity and may cease before the first sound. Auricular systole is a relatively unimportant event in association with these murmurs, and while it may cause an actual presystolic accentuation of the rumble this is by no means always the case. In rapid action of the heart, however, with shortening of diastole, the sounds follow one another in such quick succession that the mitral diastolic murmur ends in the first sound, and is, therefore, presystolic in this sense and seems to be truly crescendo up to this point. If, then, the heart's action be rapid, the murmur appears to be presystolic. If, however, it be slow, one can generally appreciate that the murmur arises and reaches its maximum during the period when the greater part of the blood passes from auricle into ventricle; namely, in the early part and middle of diastole. In any event the murmur, in the absence of aortic insufficiency, is characteristic of mitral stenosis.

The sharp valvular first sound associated with the same condition—mitral stenosis—may alone justify a diagnosis, but rarely, only when it is most intense, as for instance, in cases where the sound is audible at a distance from the heart.. As a rule there must be other corroborative testimony before one is justified in interpreting a sharp first sound as evidence of mitral stenosis. There are few errors in cardiac diagnosis commoner than the assumption of the existence of mitral stenosis on the basis of a sharp first sound alone.

CONGENITAL CARDIAC DISEASE.

I shall not touch here on those murmurs which may justify the diagnosis of congenital cardiac malformations. Such murmurs, as is well known, may, notably in the case of septum defects, be the only positive evidence of cardiac abnormality.

Of manifestations which are commonly and erroneously interpreted as evidence of cardiac disease, I have spoken on another occasion:—the disproportionately large heart in the growing child; the striking movability of the normal heart which with the patient in a lateral decubitus, may give rise to erroneous inferences as to its size; the normal protodiastolic gallop—third sound—in the young; the unimportant systolic murmur in the pulmonary area; the frequency of like murmurs at the apex in the young in recumbent and left lateral postures; the loud cardiorespiratory, inspiratory murmur, so often heard around into the back; the lack of pathological significance of respiratory arrhythmia; the frequency of extrasystolic irregularities in the absence of evidence of cardiac disease.

But I have already done more than your president has asked me to do. He asked me to present a short communication on the "minimum symptoms and signs necessary to make a diagnosis of organic heart disease." I have circled carefully around the periphery of the subject, and discoursed at length on a variety of more or less relevant topics. It is high time that I should make way for those who have something more valuable to say.

1208 Eutaw Place.

Clinical Observations of the Morphology and Function of the Capillaries

By ERNST P. BOAS, M.D.,
New York,
Medical Director, Montefiore Hospital for Chronic Diseases.

The capillaries are assuming an ever increasing importance in our concept of the physiology of the circulation both in its normal and abnormal states. Since Malpighi by his demonstration of the capillary connection between the arteries and veins supplemented and completed Harvey's discovery of the circulation of the blood, the capillaries have been thought of as passive elements in the circulatory apparatus, whose chief function it is to provide a large area in which the exchange of gases, nutritive matters and waste between the tissues and the blood takes place. This aspect of the function of the capillaries is of sufficient importance to merit some emphasis.

The whole circulatory apparatus is adapted primarily to maintain the capillary flow. The regular beating of the heart, the elasticity of the arteries, the peripheral resistance of the arterioles, the mechanism by means of which the venous blood is returned to the heart, serve no useful end in themselves, if we may be allowed to speak teleologically for a moment, but are all adapted and coordinated to keep up a constant streaming of the blood in the capillary vessels. When symptoms of circulatory insufficiency arise, they may be traced to a disturbance in the blood flow in the capillaries. Thus heart failure sufficient to cause chronic passive congestion of the viscera is of significance because the stasis of the blood in the capillaries interferes with the metabolic activities of the organ involved and results in symptoms referable to malfunction of that particular viscus. The blood flow in the capillaries, therefore, is a measure of the efficiency of the circulation and should be of interest to us from that point of view alone.

In recent years another aspect of the problem has been emphasized. It has been shown beyond cavil that the capillaries are not merely passive carriers of the blood but that they have an independent and proper function and share with the heart, the arteries and veins in the dynamics and maintenance of the circulation.

The first observations that suggested that the capillaries have the power of independent dilatability and contractility were made over fifty years ago. In 1865 Stricker (1) studied the capillaries of the nictiating membrane of the frog, and saw them contract and dilate in response to mechanical, chemical and electrical stimuli. He believed that these changes were due to a turgescence of the capillary endothelium. A few years later Rouget (2) confirmed his observations, and described spindle elements in the capillary wall which had the power of contractility, and attributed to them the functional activity of the capillary vessels. In 1878 Severini (3) stated that oxygen caused contraction and carbon dioxide dilatation of the capillaries. His studies were made upon the frog and on the mesentery of the guineapig. They are of great interest in the light of the recent work of Krogh. The following year Roy and Brown (4) published their classical paper on the blood pressure in the arterioles, capillaries and venules of the frog. They, too, demonstrated the independent contractility of the capillaries.

More recent anatomical studies have shown that the capillaries are supplied with nerve fibrils. Hooker (5), among others, has demonstrated constriction and disappearance of the capillaries of the cat's ear on electrical stimulation of the cervical sympathetic nerve. It has also been proved that certain drugs act directly on the capillaries. Thus histamine produces a dilatation—and this is of considerable theoretical interest—and epinephrin and pituitrin a contraction. Nitroglycerine, too, causes a dilatation of the capillaries (6, 7).

Krogh, who has been pursuing some masterly studies on the physiology of the capillaries, has clearly demonstrated the contractile cells of the capillary wall, and by many ingeniously devised experiments has again shown the contractile power of the capillaries. He has found that the capillary bed is constantly changing and that the individual capillaries are opening and closing all the time, so that the blood flow is continually being shunted from one vessel to another. Most interesting of all are his experiments proving the hormonal control of the capillaries. He has shown that in the frog, at least, the capillaries relax and become greatly dilated when there is no pituitary extract in the blood and that the addition of minute traces of this internal secretion to the blood circulating through the part will restore the normal tone and calibre of the capillary vessels.

Krogh has also pointed out that with dilatation of the capillaries their walls become attenuated and thus more permeable to the blood plasma. The bearing that this observation has on the phenomena of inflammation and edema is selfevident.

I have enumerated all of this evidence to show that the capillaries have an active function of their own and that they are not simply passive tubes uniting the arterial and venous systems. It is apparent, therefore, that in studying the dynamics of the circulation we must consider the capillaries as one of the elements concerned in maintaining the blood flow. The corollary of this is that disturbances of the capillaries, either organic or functional, may be reflected in general disorders of the circulation.

The early studies on the capillary function were made on the web of the frog's foot, or on some transparent membrane, such as the mesentery or nictitating membrane, because only these structures lent themselves to microscopic study. The discovery of Lombard (8), that by means of a drop of oil or glycerine placed on the skin the human capillaries could be studied microscopically, opened up a new field of study. When the hand or a finger is placed on the stage of a microscope and a drop of castor oil is applied to the area of the skin to be observed and a strong light is thrown upon it from the side, the capillary loops are clearly visualized, if a magnification of about fifty to eighty diameters is used. The cutaneous capillaries are derived from the subpapillary arterial plexus which lies just below the cutis and ascend in the papillæ of the skin vertically to the surface. By the method employed, therefore, we see only the tangential aspect of the top of the vertical capillary loop. It is so short that observations of the morphology of the capillary and the blood flow are almost impossible. However, at the base of the finger nail the papillæ of the skin are flattened out and, as a consequence, the capillary loops here assume a position parallel to the surface of the skin. They can, therefore, be visualized in their whole length. That is why capillary studies are carried out chiefly at this site. The same area of the toes can be used, but the clumsiness of handling the foot makes it impractical for routine work. The oil on the skin acts just as the oil used with an immersion lens does; it avoids the many irregularities of the skin which reflect and refract the light, so that no clear image is possible.

When we observe the skin at the base of the nail in this manner, the capillary loops stand out very clearly, and we can study their morphology and the character of the blood flow through them. With the aid of a special instrument designed by Danzer and Hooker (9), which is in essence a small transparent air chamber connected with a mercury manometer, by means of which pressure can be exerted on the skin while the capillaries are kept under observation through the microscope, the blood pressure in the capillaries may be estimated.

Let us first direct our attention to the morphology of the capillaries observed in this manner. In discussing variations in structure it is always important to have clearly in mind what is meant by the normal. One sees a row of small hairpin shaped loops just proximal to the cuticle. The next row below these consists usually of shorter vessels which, in the succeeding rows, become still shorter and comma shaped. This is due to the arrangement of the papillæ of the skin described above. The disposition of the vessels and the clearness with which they can be seen depends in part on the condition of the cuticle and of the skin. If the cuticle is pushed far back by manicuring, it will be very difficult to see any long loops. If the skin is thick and scaly, visualization of the vessels will be difficult. If the skin is atrophic and the papillæ are flattened out, many rows of long vessels will be seen and the subpapillary venous plexus may be visible. One must be circumspect therefore in drawing generalizations from the capillary picture observed. The Germans have been guilty of many indiscretions in this regard. Weiss, for instance, has described capillary pictures characteristic of nephritis, arteriosclerosis and a number of other conditions. While there is some truth in his observations, his generalizations are unjustified. For the present it is safest to be satisfied with the statement that disorders that affect the structure and function of the capillaries may exhibit themselves by a change in the capillary morphology. Just as in the arteries, a change in structure usually manifests itself by a lengthening of the vessel with a consequent tortuosity in its course, so the capillaries, in pathological states, become convoluted and lengthened. This may be explained either by an actual alteration in the structure of the capillary wall, or by a disturbed innervation causing a loss in tone of the vessel with consequent lengthening.

There are a few conditions in which the capillary picture appears to be sufficiently typical to warrant especial mention. In hypertension the capillaries are usually long and thin; if much arteriosclerosis exists they are likely to be convoluted and to show figures of eight; in long standing heart disease with repeated attacks of decompensation, the venous loop of the vessel is thick; in acrocyanosis the capillaries are large, long and tortuous; during pregnancy, too, they change their shape.

I have studied eight cases of thromboangiitis obliterans. In all of them one or both legs had been amputated for gangrene developed in the course of the illness. In only two cases was I able to examine the capillaries of the toes. One of these patients suffered from pains in the leg; the other did not. In both of these cases the capillaries of the toes were normal in appearance. One of the patients had lost all of the fingers of both hands, except the thumbs, and the other one had lost the terminal phalanx of one finger; both complained of pain in their hands. Three patients suffered from pains in the hands and of these one had no radial pulse in the left arm and three patients had no pain.

No typical capillary picture was found in those patients with definite evidence of thromboangiitis of the upper extremities.

It is true the capillaries were often long and convoluted and many rows, together with the subpapillary venous plexus, were visible. This picture is seen in a variety of conditions and may be associated in part with the atrophy of the skin over the matrix of the nail bed that is so often seen in these individuals. In a few patients the capillaries were widely separated from one another and there were relatively few to the microscopic field. However, after mechanical stimulation of the skin by stroking, capillaries appeared in the clear spaces, so that the usual number could be counted.

Patient 28 was studied in September, 1921, and in November, 1922. There was no change in his condition in the interval. On both occasions it was noted that few capillary loops were visible. After rubbing the area of the skin with a blunt instrument under observation many anastomosing and branching capillaries came into view. These observations lend themselves to the interpretation that many of the capillaries were tightly contracted, permitting the passage of no blood until the mechanical stimulus brought about their relaxation.

The capillary blood pressure was normal in four cases that were studied.

Spasms of the capillaries have been observed in Raynaud's disease. Halpert describes a typical case. During the attack the number of capillaries visible is unchanged. The larger capillaries become fuller, especially the venous loop, and their contour changes; projections and strictures form. In severe attacks the capillary flow ceases but in the larger capillaries the blood is pushed through the vessel in a peristaltic-like wave. Pribram and Henius describe a similar peristalsis of the capillaries in the stage of ischemia.

With a little practice the blood flow in the capillaries can be visualized clearly. The normal flow is so rapid that it is difficult to follow. It appears rapid only because of the magnification employed for the actual velocity of the blood stream in the capillaries is 0.5 mm. a second. However, it is not the same in all of the vessels in the microscopic field and we see here and there the movement of the corpuscles up the arterial loop and down the venous one. The flow is not constant in the individual capillaries. If we fix on one vessel, we may see at first a slow halting flow. Suddenly it becomes accelerated and so rapid that the eye cannot follow it. At times the capillary may disappear from view altogether, either because it becomes closed or because the blood becomes sidetracked through anastomotic channels into adjacent capillaries. We cannot determine in the cases under observation what the cause for this variation is, but the studies of Krogh have shown that the capillary flow is determined by physiological moments. He has demonstrated (10) for instance, in the frog's tongue that the number of capillaries seen after the muscle has been in action is far greater than when it is at rest. He has also described the dilatation of the capillaries on exposure to carbon dioxide. The capillary blood flow thus responds to the needs of the tissues. It is probable that chemical stimulation by metabolic products and particularly by the relative concentration of carbon dioxide is one of the determining factors in this local variation of the degree of capillary filling.

It is important to realize that local changes in the circulation may occur quite independently of the systemic circulation. Thus in the vasomotor disorders, such as acrocyanosis, it can be clearly demonstrated that during the time that the hands are cold and blue the flow in the capillaries is almost stagnant or, at best, very slow (11). In the same patient when the hands are warm and pink, the blood flow in the capillaries is rapid and uninterrupted. It is interesting to study a patient whose hands are cold and cyanotic and note the sluggish blood stream, and then to immerse his hands in hot water and to see the consequent rapid streaming of the blood. Such patients are often told that their cold hands and feet are due to a poor circulation, a statement which inferentially reflects on the heart. Their disorder is a purely local affair, dependent upon disturbed innervation of arterioles and capillaries.

Dale (12) and Cannon have shown quite conclusively that in shock the essential disorder is a paralytic dilatation of the capillaries. As a result of this paralysis the blood accumulates and becomes pooled in the capillary vessels; the patient, so to speak, bleeds into his own capillaries and there is an insufficient amount of blood in the heart and arteries to carry on the circulation. Hooker (5) has demonstrated photographically the dilatation of the capillaries following histamine shock and recently Freedlander and Lenhart (13) observed it clinically in several patients who were in shock. This is the most striking illustration of the manner in which disorders of the capillaries may disturb the circulation even when the heart and arteries are normal.

Recent studies suggest that capillary paralysis induced by toxemia is responsible for the circulatory failure that accompanies many infections such as pneumonia and peritonitis (14). No other satisfactory explanation has been offered. Indeed, many experiments have been performed to show that neither the heart, the vasomotor centre, nor the arterioles are at fault.

Another interesting phenomenon which is due to the functional activity of the capillaries is the white line of Sergent, which, incidentally, was first described by Marey in 1858 (15), and which has, on insufficient evidence, been called a sign of adrenal insufficiency. The pallor of the skin in this phenomenon is caused by a constriction of the capillaries which become emptied of their blood.

It will occur to everyone that the method of direct observation is well adapted to demonstrate pulsation of the capillaries in the conditions giving what is known as the capillary pulse. I have studied a large number of such patients and have been able to demonstrate that no matter how clear the clinical evidence of systolic flushing of the skin may be, the capillaries do not pulsate (16). In other words, what we have been in the habit of calling a capillary pulse is not a capillary pulse at all. The phenomenon must be due to an exaggerated pulsation of the small arterioles and possibly of the small venules of the skin. We should, therefore, to be accurate, discard the term capillary pulse and speak of the systolic flushing of the skin.

The most interesting aspect of the study of the capillaries is the study of the capillary blood pressure. This has many theoretical as well as possibly some practical bearings. No accurate methods of determining the capillary pressure were at hand until Danzer and Hooker described their microcapillary tonometer. Most of the previous methods depended on the paling of the skin as the end reaction in the measurement of the pressure in the capillaries. The two authors mentioned above pointed out the fallacy of this criterion and by means of their instrument were able to determine the exact point at which the blood flow ceases in the capillaries when pressure is applied to it. They determined that the normal capillary pressure is about twenty to twenty-five mm. of mercury. I have studied a large number of patients with the aid of this instrument and have been able to confirm their studies and to make a number of interesting observations (17).

In a number of cases of severe myocardial insufficiency the capillary pressure was low, the flow sluggish and the capillaries dilated. This is corroborative evidence that back pressure effects with heart failure are not determining factors, but that the sluggish flow is caused by a diminished *vis a tergo*. Furthermore, it suggests an explanation of cardiac edema—as determined by the increased permeability of the dilated capillaries carrying a sluggish current of blood.

The most interesting group of cases are those with hypertension. With Dr. S. Frant and Dr. I. Mufson I have carefully studied forty-seven such patients. Of these twenty-eight had a normal or a low capillary pressure, while nineteen had a high capillary pressure. A normal pressure was one under 30; the high pressures ranged from 30 to 90. The patients were studied clinically from every angle, yet we were unable to establish any clinical criteria which would distinguish the two groups of cases. The degree of hypertension, the kidney function, the duration of the illness, in fact every possible factor was carefully considered, yet no definite rule could be established. In other words, we were presented with the problem—why has one group of patients with hypertension a high capillary pressure and another a low one, notwithstanding the fact that they present similar clinical pictures?

These observations were made a year ago. We have within the last month looked up all of the old cases to determine what has become of them and have repeated the determination of the capillary blood pressure on those who were still alive and accessible. We are not yet prepared to present our final conclusions. It is worthy of note, however, that of the nineteen patients with a high capillary pressure, eight died within a year of the first observation of their high pressure. Of the twenty-eight with a normal or low capillary pressure only five died. It would seem, therefore, that a high capillary pressure indicates an unfavorable prognosis. An adequate explanation of our observations on capillary blood pressures is not as yet forthcoming. That the facts are of significance, I am convinced.

CONCLUSIONS.

In the light of all of the evidence that has been gathered in recent years, we must revise our opinions of the rôle that the capillaries play in the normal and disordered circulation. They are concerned, together with the arterioles, in the maintenance of the peripheral resistance. It may be that their active contraction assists in the progress of the blood from the periphery to the heart. They respond to the local needs of the tissues by dilatation when there is an excess of carbon dioxide; by constriction when this is relieved. They are further under control of the central nervous system and respond to certain stimuli by contraction, thus affecting the blood supply to the part in question. They are probably also influenced by certain internal secretions.

The independent functional activity of the capillaries is responsible for many of the phenomena observed in the sick. Among the most striking of these may be mentioned shock, the circulatory failure accompanying many acute infections, dermographia, urticaria, vasomotor disorders of the extremities including Raynaud's disease. The color of the skin is determined in large part by the degree of filling of the capillaries and venules. A constriction of these vessels will produce a pallor of the skin which may be mistaken for anemia. The capillaries undoubtedly play an important part in the causation of edema. Their rôle in the hypertensive states is still a matter for speculation, but there seems to be no doubt that they are intimately concerned in certain of these conditions. The capillary blood pressure appears to be of some prognostic value—a high pressure being of grave significance. The capillaries undergo morphological changes in the course of disease, just as do the larger bloodvessels.

We are still on the threshold of our knowledge of the pathological anatomy and physiology of the capillaries, but we have learned enough to assign to them an important rôle in the causation of circulatory disorders and to encourage us to seek further light on their normal and abnormal function.

The Present State of Our Knowledge of Quinidine Therapy in the Treatment of the Fibrillating Auricle*

By LOUIS FAUGERES BISHOP, M.D., SC.D., F.A.C.P.,
New York.

INTRODUCTION.

This paper is to be more in the nature of an appraisal of the value of a new procedure than the report of personal experience and I have drawn freely upon other authors for their conclusions.

There is no question but that the application of quinidine in the treatment of auricular fibrillation has proved to be extremely interesting. It differs from the previous treatments of fibrillation in that it restores function to a type which corresponds to normal. We already had in the treatment of fibrillation by digitalis the most striking example of therapeutic effect in all medicine. It is unfortunate that the new measure should not have pertained to a problem less well covered by therapeutics.

By the proper adjustment of digitalis thousands of persons with fibrillation of the auricle have had their capacity to work restored to them. The slower rhythm in the heart does not, however, conform to the sinus type but remains irregular.

Since fibrillation is a relatively rare disease each general practitioner has a chance to observe only a few examples of this disease. We must, therefore, look to those who have had an extensive experience in this field to settle some interesting and important questions that have arisen.

The first question is whether, when normal rhythm is restored for a time, the benefit to the patient is strikingly better, in the long run, than when the rate has been promptly adjusted.

A danger of quinidine therapy is that embolic infarction of internal organs is of frequent occurrence when old cases are treated. Anyone, therefore, who is familiar with the benign course of fibrillation of the auricle under digitalis therapy would hardly recommend quinidine in instances where important degeneration of the heart muscle is present. The use of quinidine is dangerous and has brought about comparatively few permanent restorations of rhythm. Everyone who handles many persons with auricular fibrillation knows how well many of them do without restoration of rhythm. It is difficult, indeed, to draw any conclusions as to the real effects of quinidine because the natural history of this disease reveals many instances of remittance of attacks extending over long periods of time without any direct therapeutic explanation.

Perhaps one of the most judicious appraisals of the value of quinidine is given in the article of C. C. Wolferth (30). He says: "The use of quinidine in the treatment of auricular flutter and fibrillation is to a certain extent, in an experimental stage, but certain points in respect of the types of cases in which the drug may be employed and details of treatment have been established. The most favorable cases for treatment are those with, 1, relatively good heart muscle and at least fair compensation, and 2, flutter or fibrillation that has been present only a short time. In cases with good heart muscle the restoration of sinus rhythm with the abolition of the mechanical disadvantage to the heart of such profound disturbances of its mechanism as fibrillation or flutter, may be expected to yield good results. But the use of the drug in patients with weak heart muscle is not so likely to be beneficial. Not only is it dangerous to use so depressant a drug as quinidine in such cases, but the chance of restoring the normal rhythm is much less. It is doubtful whether the advantages that may be gained by the restoration of normal rhythm in a comparatively low percentage of cases in this group counterbalances the disadvantage of still further disturbing the compensation in some cases and the possibility of meeting disaster.

"The importance of the duration of flutter or fibrillation has been questioned. It is agreed by most observers that if the abnormal rhythm is of recent origin it is much more easily removed. Not only may a small amount of quinidine be sufficient to restore the normal rhythm, but apparently the recurrence of fibrillation is more easily prevented in these cases.

"In the management of patients under quinidine therapy a close observation should be maintained. The possibility of the rapid development of alarming symptoms makes it necessary that immediate attention be available. Consequently the patient had better be in a hospital or under the care of a well trained nurse. On account of the abrupt changes in the cardiac mechanism it is a decided advantage to make frequent electrocardiographic examinations.

"The sulphate of quinidine has been found preferable to the pure alkaloid in treatment on account of the insolubility of the latter. Thus far the drug has usually been given by the mouth. Because of the possibility of hypersusceptibility of the patient, one or two small preliminary doses, such as 0.2 gram, should be given. If any symptoms develop from such small amounts the treatment should not be undertaken. If there is no hypersusceptibility, larger doses may be given, beginning with approximately 0.4 gram three times a day and gradually increasing to one gram three times a day, in a person of average size. It is probably not worth while to continue a course of treatment more than ten days. After a rest period a second course may be instituted if the first is unsuccessful.

"As soon as normal rhythm is discovered the large doses of quinidine should be discontinued. The problem then changes to one of maintaining the normal rhythm. Thus far the results have not been brilliant, but this may be due in part to lack of knowledge of the proper amount of quinidine the patient should take. It has been customary not to give more than 0.2 gram twice a day. A great deal of work remains to be done in this field. It would appear reasonable to avoid any strain on the heart for a long time after the restoration of normal rhythm, since a strain might be expected to help convert the mechanism back to fibrillation.

---

*Read before the Meeting of the American Therapeutic Society, Washington, D. C., May 2, 1922.

"The types of disagreeable effects that may occur during quinidine administration have already been stated. In the present state of our knowledge extreme caution should be observed in giving the drug if any of them develop. Such symptoms as increasing weakness, dyspnea, dizziness or precordial distress or manifestations of cinchonism, such as ringing in the ears, deafness or stuffiness in the head, should call for withdrawal of treatment. The development of a rapid ventricular rate presents a problem. If the fibrillation has been converted to flutter or a transition stage between fibrillation and flutter it is desirable to continue the treatment if possible in spite of tachycardia, since the prospect of the return of normal rhythm is good. But if symptoms of cardiac embarrassment supervene the treatment should be discontinued. Likewise should tachycardia develop before the course of the excitation wave in the auricle has been much altered the treatment would better be stopped.

SUMMARY.

"1. Studies of the physiological action of quinidine have shown that it is a cardiac depressant influencing chiefly the functions of contractibility, excitability and conductibility.

"2. Quinidine has been found effectual in restoring the normal rhythm in auricular fibrillation and flutter in slightly over one half the cases thus far reported.

"3. Quinidine therapy is still in the experimental stage. If it is used there must be careful selection of cases and constant observation during the course of treatment."

HISTORY AND REVIEW OF THE LITERATURE.

In 1853 Pasteur isolated quinidine from the cinchona bark. Quinidine is an alkaloid and an isomer of quinine. In the past it has been used as a tonic and as an antimalarial drug. Quinidine was characterized in the following manner in the *Epitome of the United States Pharmacopœia and National Formulary:* "At one turn recommended as a cheap substitute for quinine. Inferior and obsolete."

Quinine in combination with digitalis had been given empirically in the treatment of heart disease prior to Weckenbach's experiments of 1914.

Weckenbach experimented with quinine and its effect on fibrillation but without constant results. He wrote in connection with one of his reports: "I have since this experience repeatedly given quinidine and had it given, but only in one other case have caused the cessation of the fibrillation."

In 1918 Frey studied quinine, quinidine and cinchonin from a pharmacological viewpoint. He found quinidine combined with sulphate to be the most effective therapeutic agent in the relief of auricular fibrillation.

Frey made subsequent observations in 1921 and reported his results in fifty cases as follows: Out of fifty cases, twenty-one returned to normal temporarily. In six, the fibrillation became a regular flutter. He says that in the majority of cases the auricular fibrillation was benefited, but only four per cent. were relieved where the arrhthymia had continued over a period of one year. He states that cases of auricular fibrillation complicated by heart failure did poorly under quinidine therapy.

Levy in a recent report on the effect of quinidine on the mechanism of the auricle gives several illustrations of cases where the normal cardiac mechanism in auricular fibrillation was restored. However, at the end of his article he states that from his own survey and from the literature the factor which determines whether quinidine is successful or not is as yet not quite clear. He believes it is best to administer as much of the drug in as short a period of time as is consistent with the factor of the safety of toxicity.

In the past three years there have been many clinical investigations as to the effect of quinidine on auricular fibrillation. Among the most significant reports are those of Arnell, Benjamin and Van Kapff, Boden and Neukirch, Drury and Iliescu, Faber and Jenny, Klewitz, Levy, Romberg, Cohn, Cheinisse, Clerc and Pezzi, Heffter, Lewis, Meldolesi, Schrumpf, Arillage, Guglielmetti and Waldorp. At the present moment there are many physicians who are carrying on research work in this field from a clinical as well as a laboratory point of view.

White in his recent article entitled The Action of Quinidine Sulphate in Heart Disease to Abolish the Circus Movement in Auricular Fibrillation, says that "Of a total of 228 cases in the literature, including the thirty-five new cases reported on in the present paper, 130 have shown a restoration to normal rhythm (fifty-seven per cent.)."

If one studies any drug purely from the point of view of cardiac recommendation and regard these statements alone one will be led to believe it has important activities. Therefore, much of the literature must be dismissed as being mere conventional repetition. Nevertheless, a long time ago there were individuals who had a spcific belief in the benefit of quinine in heart disease. Many physicians who are closely connected with quinidine therapy in hospital work at the present time do not make as great claims for the drug as would seem from the quotations from their papers.

Few authors have stated that results were permanent, although some observers believe that by continuing the drug in small doses a prophylactic influence may be exerted so that recurrent attacks of fibrillation are further separated and of shorter duration. One difficulty in the matter is that not many men have studied fibrillation in a sufficient number of cases to have a matured judgment as to the natural history of the condition.

NATURAL HISTORY OF AURICULAR FIBRILLATION.

The fact that fibrillation begins with intermittent short attacks which gradually become of longer duration and finally become permanent, is not always appreciated. Therefore, if a case of fibrillation is treated in the early stages the intermissions which are part of the natural history may be taken as therapeutic results.

Another element of error is that a person may be observed a number of times during a test and never be seen during the intermission so that the impression may be gathered that it is a case of continuous fibrillation when, in truth, it is an intermittent type.

I had under my care an old man who was suffering from fibrillation of the auricle. He was under observation for several months and then disappeared. Two years later he returned for reexamination and his heart was found to be normal in rhythm.

Sometimes apparently firmly established fibrillation of the auricle returns to normal rhythm without specific treatment. These sudden recoveries may be very rare just as spontaneous cure of cancer is most unusual, but there are a sufficient number of these cures to make a single therapeutic observation of uncertain value.

Quinidine has many characteristics which make it a promising remedy for the diseased auricle as in all probability this part of the heart is the seat of disturbance of chemical function with the possibility that there is an underlying infection as a cause. Whether or not the improvement of fibrillation under quinidine proves to be of great clinical importance, the question is bound to arise before the profession whether this remedy should be used for the action which is usually called tonic effect.

In malarial countries it became the custom to use quinine as a tonic probably on the ground of analogy and since people suffering with malaria were improved so much in general health it was thought the remedy might be used for general debilities. A difficulty of interpretation arises from the fact that a heart with chronic fibrillation is subject to improvement and deterioration of condition in the ordinary course of life, irrespective of remedy.

The following data as to the action and uses of quinidine are given in the *Journal A. M. A.* (32).

"Quinidine is obtained from cinchona bark as a byproduct in the manufacture of quinine, to which it is closely related, being the stereoisomer of quinine.

"*Actions and uses.*—Quinidine, like quinine, is a protoplasm poison. It affects protozoa more than bacteria, but less powerfully than quinine. At one time it was used, to some extent, as a substitute for quinine because it was then much the cheaper.

"Quinidine acts upon the heart in such a manner as to bring about cessation of fibrillation of the auricles in a certain proportion of instances. Quinidine and other cinchona alkaloids, are the only drugs known to have this specific effect. The pharmacology of the drug has not been thoroughly investigated; but it is probable that quinidine increases the refractory period of auricular muscle and decreases its irritability and the rate of conductivity. In large doses in the isolated hearts of rabbits, it slows the heart rate and causes paralysis of the auricle; shortens the auriculoventricular conduction time, and results finally in paralysis of the ventricle. Quinidine is used to restore the normal rhythm of the heart in cases of auricular fibrillation. This has been brought about in approximately fifty per cent. of the reported cases in which the drug has been used. It is apparently most efficacious in the cases of fibrillation of short duration or of the paroxysmal type. It may also stop fibrillation of several years' duration. It is least effective in cases of fibrillation with marked cardiac insufficiency. Quinidine is not without some unpleasant and even dangerous effects. Some patients appear much more susceptible to its toxication than others. The untoward symptoms brought about by its use in these patients are nausea, vomiting, convulsions, palpitation, headache, faintness and flushing. In most cases following the administration of the drug, the pulse increases in rapidity before the normal rhythm is established. In some cases the effect of the drug is restricted to this alteration of rhythm. In a few instances, such serious results as rapid idioventricular rhythms (ventricular tachycardia) have been initiated during the course of therapy. Toxic effects may appear after the establishment of a normal rhythm. Some cases have been reported in which sudden death occurred a short time after the drug had been stopped. The effect of the drug is not known to be permanent; but the normal rhythm, when once established through the action of quinidine, may last from a few days to several months.

"Quinidine is generally administered as quinidine sulphate. Commonly 0.2 gm. (three grains) of quinidine sulphate is given as a preliminary dose and is repeated after two hours to determine the patient's susceptibility to the drug, therapeutic administration is begun on the following day when from 0.2 gm. to 0.4 gm. (three to six grains) is given from three to five times daily, for one to three days. As a rule, if the establishment of the normal rhythm can be effected, the change occurs after from one to three days' treatment. The maximum dose per day advised by most authors is from one to two gm. (fifteen to thirty grains). If toxic symptoms occur, the administration of the drug should be discontinued."

The type of person in whom it is probably justifiable to try quinidine therapy is one in whom fibrillation has recently developed and who has been put to bed and the heart brought under control by digitalis medication. If the attack of fibrillation is of recent origin the chances for the restoration of rhythm are good and the danger not great.

On the other hand, quinidine should not be used where there is marked degeneration of the heart muscle and where the condition is of long standing.

It is doubtful to my mind whether it should be attempted in that large class of patients who come for examination once in a month or two, who have chronic fibrillation and who are in very good condition on the moderate use of digitalis. These people do so well over such long periods of time that one does not feel justified in hospitalizing them in the manner necessary for safe testing of quinidine.

We have not found, as a matter of practice, that the administration of small doses of quinidine in ambulant cases produces satisfactory results.

To coin a word from an analogous one I would say that the quinidization of fibrillation patients should be a hospital procedure. A number of alarming attacks in the course of the process is such that immediate help ought to be near at hand while quinidine is being applied.

It is fair to conclude that final determination of the true value of quinidine in cardiac therapy cannot be looked for in the near future unless some one is fortunate enough to make an important discovery as to the true mechanism of the operation of the drug. It, therefore, behooves conservative men at present to withhold judgment on the ultimate effect of quinidine in auricular fibrillation.

The Blood Pressure in Angina Pectoris

By ALEXANDER BLACKHALL-MORISON, M.D., F.R.C.P.,
London, England,
Consulting Physician to the Royal Northern Hospital; Cardiologist to Mount Vernon Hospital.

In the third volume of the *Edinborough Hospital Reports,* issued in 1895, there is an article by myself under the title of this paper. In the fourth volume of the same reports, the late Dr. George A. Gibson writes on Cardiac Pain and Its Relief. Twenty-eight years have elapsed since these articles were written. Truly life is short and art long. There is a painful interest in examining such records, as I have done preliminary to writing this article, for those who survive and continue to cogitate on problems which equally exercised friends who now rest from their labors. In the interval much cardiac work has been done but the nature of Heberdens's disease still remains abundantly debatable in many particulars.

The instrumental estimating of blood pressure as we make it today was not at that time practised although conclusions reached on other grounds could be equally valid; some think more. In the article I refer to I demonstrated from auscultatory and sphygmographic investigation that in aortic valvular angina there was a fall of blood pressure during the attack which rose on ventricular recovery.

The precise cause of the pain in cardiac angina is still obscure in many cases. That it is not the same in all may be asserted with some confidence. That its appreciation and expression lie in the nervous system requires no argument. The fount and origin of the pain, however, may be in muscular failure or abnormal irritability or in local lesion which is usually vascular. To maintain this last view is at the moment rather heterodoxy but the heterodoxy of today is often the orthodoxy of tomorrow and the future at times finds itself in agreement not with the views of today but with those of yesterday, that is, with the past. If art is long, opportunity also is fleeting and judgment remains difficult, to quote the immortal aphorism of the Father of Medicine.

Discounting the element of mechanical vascular resistance which has been so ably dealt with by Professor Russell in his work on *Arterial Hypotonus, Sclerosis and Blood Pressure,* here is a prognostic value in determining the approximate blood pressure of the suspect of angina pectoris which has not, so far as one can gather from the literature of the subject, been sufficiently appreciated.

If one has had an opportunity of observing these cases over a term of years, one gains experience which is of practical importance. True cardiac angina appears nearly always to be ultimately fatal, however long the dénouement may be postponed. A period of fleeting anginal symptoms, so slight it may be as to appear negligible, may subside and only recur from time to time in such a degree as to render its diagnosis uncertain and even find seeming explanation in some other visceral hypothesis of more hopeful augury. But the day usually comes in angina vera when the full agony of the classical syndrome leaves little doubt as to the condition with which we have to deal. If this has not an immediately fatal issue all pain may subside, a patient may find himself subjectively in complete comfort and objectively may or may not show any appreciable difference in his usual heart rate or rhythm. But, if we find an instrumental estimation of his approximate blood pressure, though our man to our knowledge has habitually had a blood pressure reaching to a certain height, reveals a notable fall in that respect after an anginal attack, this incontestible evidence of experience justifies our holding the gloomiest prognosis. I may illustrate my meaning by concrete examples.

On May 2, 1921, I was hurriedly summoned to H. M., sixty-nine years of age, whom I had known for forty years and who occasionally consulted me. Twenty years previously he had complained of pains in the chest, which were reported as anginal but they were slight and transient. Nauheim was in vogue at the time. He visited it, liked the place, and disported himself in the warm salt water. Then for several consecutive years fished in the Teich and spent quite a pleasant holiday with apparent benefit at that Teuton Bethesda.

After a time his thoracic discomfort subsided, he conducted business regularly and rarely consulted me. I saw him on July 20, 1920, and found his blood pressure to be 150, diastolic 80, which for a man of sixty-eight might be considered almost normal and certainly indicating no peripheral vascular sclerosis. Examination showed nothing amiss with his heart and lungs beyond a little rhoncus in the latter. His urine was normal and beyond a certain hypersomnial tendency, which he had always manifested, his condition was in no way serious. He made no special complaint of the chest pains, conducted his business comfortably and tooted his gig through Hyde Park regularly curbing his mettled steed without difficulty.

On May 1, 1921, the day prior to my hurried summons to him, when I found him in angina, he had driven a coach and I believe "four" from Richmond to London, retiring to bed in his usual health. The attack occurred in the morning before breakfast. The occurrence of fatal angina after sleep when one would expect refreshment to be at its height is not unusual.

I found the patient in severe thoracic pain which was chiefly felt in the upper central back with radiation first into the left and later into the right arm. His skin was cold and moist, the pulse 60 and intermittent and he expressed the fear of impending death. I injected hypodermically one sixth grain of morphine with 1/120 of a grain of atropine and one sixtieth grain of strychnine. He then inhaled with relief five minims of nitrite of amyl which produced a normal acceleration of pulse. He had no organic heart block. Carefully watched for some hours he regained general comfort and lost his apprehension of immediate dissolution. He was kept strictly in bed never leaving it for any purpose until his death, which occurred ten days after the attack which never recurred. In the interval he had regained complete subjective comfort, took his food well, slept soundly and showed a regular pulse which ranged from 72 to 92.

On May 9th I took his blood pressure and found the systolic reading to be 95 and the diastolic 70. As he was apparently quite comfortable, his continued confinement to bed was considered scarcely necessary by his surroundings but I pointed out that the blood pressure had fallen to that of a child and that he would probably die in his chair if he sat up. He therefore postponed rising.

On May 12th he had passed a comfortable night, taken breakfast, seen a man on business and read his newspaper. He then said he felt rather tired and would lie quietly for a time. Within a quarter of an hour he died quite painlessly, having shortly before death had a pulse of 80.

Soon after attending the patient H. M., referred to above, I was asked to see, in consultation with a practitioner in the north of London, a gentleman who had had several attacks of angina pectoris. A fortnight previously he had also seen another physician who had found his blood pressure to be 130-140. On meeting the medical attendant I inquired what the blood pressure measured and was told that the last noted was as stated. The day on which I saw the patient he had been in his garden and was not in bed when I called. He had proposed consulting me at my own house, and had an attack the day before I was sent for, and it was thought prudent that he should avoid the journey. I found his blood pressure to be 80.

The patient was not at the time in pain, thanked me at the conclusion of my visit for my examination and advice, asked me to mention my fee to his family and stated he would send me a check in the course of the same evening. He died a few hours after I left him. The ailment in this case was familial. His father had died similarly.

From the days of Latham's classical case, that of T. A. (Thomas Arnold of Rugby, several of whose descendants also died of the same disease), to the present time, the sudden overthrow of a heart which had done its work apparently well until the moment of its being struck by the severe pain of angina, has been a notable phenomenon and its explanation has still to be found. It appears as though a certain blunting of the irritability of the heart muscle is induced by the shock of pain which, nevertheless, is not incompatible with continued rhythmical contraction and at times although not always with little disturbance of rate. Moreover, all evidence of cardiac failure as denoted by pulmonary hypostasis may be quite absent. Yet ventricular power is manifestly failing and the low record of systolic blood pressure and its approach to the diastolic is a noteworthy clinical experience and an almost certain augury of approaching death.

These views were expressed by me in a discussion following the reading of a paper on angina pectoris before the Medical Society of London in 1921 and were also fully related in a letter published in the *British Medical Journal* on December 31st in the same year. Similar opinions have since been published by Professor Latembacher, of Paris, who also quotes Paquez as agreeing with him. (*Medical Times and Circular,* January 10, 1922.)

The facts I have narrated suffice to indicate the importance of determining the approximate blood pressure after the anginal seizures although every precaution may, at times, fail to avert a fatal issue.

14 Upper Berkeley Street, W. I.

Factors Concerned in the Production of Heart Sounds and Murmurs*

By E. I. FOGEL, M.D.,
Cincinnati, Ohio.

Sound is produced when a body is thrown by a blow or by other means into a state of vibration (1). It is most simply understood in the vibration of a cord or membrane under tension, and the tenser the body the more likely it is to produce sound, and that of a higher pitch. Thus it is that the tense violin string is made to produce sound when the bow is pulled across it, and so is the tense drum membrane made to vibrate when struck with the drumstick. Similarly do the vocal cords when made tense by the muscles of the larynx and then brought into vibration by the air current, produce sound. In seeking the cause of normal and abnormal heart sounds the same physical conditions, namely, a cord or a membrane under tension, must necessarily be looked for; and in this paper I shall endeavor to show that all intracardiac sounds are produced by similar means and in similar fashion.

There seems to be but little difference of opinion as to how the second sound of the heart is produced. With the beginning of relaxation of the ventricle after the end of systole, when the pressure on the proximal sides of the semilunar valves is lessened, the blood pressure in the aorta and pulmonary artery, which had already been keeping the aortic and pulmonary rings tense, causes the sudden closure of the semilunar valves. The quick closure of these valves, the rings of which are already tense, causes them to vibrate, producing the characteristic second sound. A similar sound is produced by the paper flapper made by children when the valve is suddenly opened with a quick motion of the hand. We are not justified in regarding the vibration of the arterial column (2) as one of the causes of the second sound; because, while the arterial column may slightly modify the sound, it only transmits the vibrations as the air column does when passing the vocal cords.

---

*From the Department of Pediatrics, College of Medicine, University of Cincinnati.

A considerable difference of opinion, however, exists as to how the first sound of the heart is produced. Nearly a century ago C. J. B. Williams (3) and somewhat later Ludwig and Dogiel (4), after experiments upon hearts whose blood had been removed, believed that the first sound was largely muscular, and upon these experiments we have based our present interpretation of the first sound. The experiments of Williams are open to question, for we cannot be sure that he eliminated the auriculoventricular valves; and even he, a short time after publishing these experiments, agreed that these valves must be a great factor in the production of the first sound. The interpretation of Ludwig and Dogiel's experiments have also been rightly criticized by Pezzi (5), so that there are no conclusive experimental facts to show that the first sound is even partly muscular. The sounds heard in all the experiments were considerably weaker and were undoubtedly due to causes other than the contraction of the ventricles. The weak heart sounds heard by Williams in part of his experiments may have been due to the closure of the tricuspid valve, and in others by that part of the auriculoventricular valves not compressed by his fingers. It is also possible that these valves were ballooned and closed by the air compressed by the contracting ventricles. On the other hand, Sibson and Broadbent (6) found that in the exposed heart the tying off the venæ cavæ caused the first sound to disappear, so they ascribed the first sound to the movement of the auriculoventricular valves. Most physiologists, however, believe both factors to come into play in the production of the first sound. Yet, can we accept this as truth?

Much explanation is necessary to show how the socalled muscular sound is produced; for if the contraction of the heart is considered a single contraction and not a series of contractions or tetanus as in voluntary muscles, there should be no muscular sound at all (7). Even if it is a series of contractions we could expect a sound but scarcely audible (8). There are much larger muscles in the body than those of the ventricles and their contraction is by no means accompanied by so great a sound as the first sound of the heart. Besides, even this sound is probably due to the vibration of the tendons and the bones to which they are attached. Nor do we find anywhere in nature a similar soft body producing so great a sound. However, innumerable instances can be pointed out where cords or membranes cause sound.

The first sound of the heart is caused by the vibration of the auriculoventricular valves and chordæ tendineæ, i. e., membranes and cords, which are made tense and set into motion by the blood stream thrown against them by the contracting ventricles. Perhaps a more important factor than that of the valves are the chorda tendini. With the closure of the valves and the contraction of the papillary muscles, the chordæ tendineæ are suddenly made tense by the pull from both ends causing them to vibrate. Take a cord or handkerchief in both hands and quickly stretch it and you will get a sound similar to the lub of the first sound. The intimate connection between the chordæ tendineæ and the auriculoventricular valves undoubtedly causes them to vibrate together. The auriculoventricular valves may be compared to the membrane of a drum, the blood stream to the drumstick and the ventricular muscle to the arm. No one considers the arm the direct cause of the sound produced, but the vibration of the drum membrane.

Clinical evidence also tends to prove that the auriculoventricular valves are the cause of the first sound. There is really not so much difference between the second sound called valvular, and the first erroneously called muscular, except that the first is lower in pitch and longer in duration, what we would expect from a larger membrane. In the fetus no difference between the first and the second sound can be distinguished; in the infant, hardly any; it is only in older children and adults, where there is a greater difference in the size of the valves, that any appreciable difference between the sounds can be noted. In mitral insufficiency the first sound is often replaced by its systolic murmur, probably because there is not enough of the valve to vibrate or to catch the blood stream. If the first sound of the heart were due mainly to the muscle, the hypertrophied muscle of mitral insufficiency would cause a much louder first sound. In comparing some of Einthoven's phonogramic tracings (9) of the normal sounds with those of mitral insufficiency, we find that the amplitude of the vibration of the first sound is much smaller in the latter than in the normal. Here too, if the first sound were muscular, the hypertrophied muscle would show greater amplitude of vibrations. In extrasystole, the muscular contraction of the ventricle is often so weak that it cannot force the aortic valves open, yet a fairly loud first sound can be heard; whereas, if the first sound were muscular we would expect hardly any sound at all. Under ordinary conditions, however, the intensity of the first sound does correspond to the force of the contraction of the ventricle because the amplitude of the vibration of the valves and chordæ depends upon the force with which the blood is thrown against them by the contracting ventricles.

Many theories have been advanced to explain the cause of the third heart sound. The only definite fact regarding this sound is, that it occurs at the time of auricular systole. At that moment the muscular rings of the pulmonary veins contract, forming pseudovalves which however do not completely close the orifices. The blood, regurgitating into the veins sets the rings into vibration, producing the soft third heart sound.

Keeping the physics of the production of sound in mind, let us approach the causes of some abnormal heart sounds. Mitral insufficiency can be taken as an example of all insufficiencies. With the contraction of the left ventricle, part of the blood is propelled through the insufficient mitral valve. The mitral valve, a thin membrane, made tense by the ventricular pressure, is made to vibrate by the regurgitating blood, just as the tense violin string is made to vibrate when the bow is drawn across it by the arm. The character of the murmur, whether harsh or soft, will depend upon the thinness and regularity of the edge of the valve. If thin and regular, the murmur is musical; if rough and calcified, more noisy in character. Similarly will a moderator band (10) in the heart, which is thin and regular, when made tense, vibrate and produce a musical sound similar to that produced by the vibration of a string of the harp or banjo.

The problem of a stenosis is, in some ways, similar to the problem of an insufficiency. We have a muscle propelling a stream of blood through a tense membrane, causing it to vibrate. But there is this difference, in an insufficiency the murmur is of decrescendo type, in stenosis the murmur is, at least in its beginning, crescendo, i. e., increases in volume and in pitch. Let us take mitral stenosis as the example. Neuhof (11) mentions that the presystolic murmur of mitral stenosis seems crescendo in character, but that the electrocardiograph sound records tend to indicate that the stenosis is crescendo because it is so near the first sound, yet practically all observers agree that it is distinctly crescendo in character. In aortic stenosis too, but to a lesser extent, the murmur is in its beginning crescendo in character. Gairdner, MacKenzie, Joachim and Hirschfelder, Einthoven and others (12) asserted that the presystolic crescendo murmur of mitral stenosis is produced by the systole of the left auricle driving the blood forcibly through the narrow mitral orifice and that it therefore takes place at the end of auricular systole. Ormerod, Barclay and others (12) state that it occurs in the early ventricular systole. Lately Reid (13) doubting the common belief that the presystolic murmur is produced by auricular contraction, seeks to explain that it is early systolic in time. Otto V. Hoffman (14) seeks to explain this murmur by the auricular blood stream pushing itself through and into the already partially filled ventricle. These contentions may explain how a murmur may be produced but not how a crescendo murmur is caused. D. W. Samways (15) believes that the "murmur is crescendo in character because the auricle can exert an ever increasing pressure on its contents as it contracts, because theoretically the pressure can increase inversely as the cube of the decrease in diameter." But the same condition exists in insufficiencies also, so that all heart sounds should be crescendo in character instead of decrescendo, and if his postulate were true the aortic stenosis with its larger and more powerful ventricle should give us a more marked crescendo tone at the aorta than the auricle does at the mitral. But the same crescendo presystolic murmur can be explained simply according to the physics of sound.

Take a violin and while drawing the bow across the string (use the G), bring the string quickly to a greater tension by turning the key, and you will produce a crescendo tone, i. e., a tone increasing in volume and in pitch. We have a similar condition in mitral stenosis. D. W. Samways (15) brings "considerable evidence to show that the contraction of the auricle normally overlaps that of the ventricle, lasting probably till the moment of the opening of the aortic valves; that in cases of mitral stenosis this overlapping tends to be still further prolonged, invading, therefore, the expulsive portion of the ventricular systole; that the murmur of mitral stenosis (presystolic) goes up to and into ventricular systolic time because the blood flow does likewise." In mitral stenosis as the blood is being forced into the ventricle by the contractions of the auricle, the mitral valve takes the form of a funnel with the convexity into the ventricle. At that moment a smooth diastolic murmur, which usually is decrescendo in character as in insufficiencies, takes place. This is due to the vibration of the mitral valve. The next phase is the beginning ventricular systole. The auricle being not yet finished with its contraction and the ventricle having already begun, we have, therefore, a rapidly increasing tension in both auricle and ventricle bringing pressure on both sides of auriculoventricular ring, thus stretching it and the base of the valves; making the valves more and more tense, producing a crescendo tone. The valve straightens out as the diaphragm does in inspiration. The mitral valve can also be compared to the membrane of a kettle drum whose pitch is raised by tightening the membrane at its ring. The presystolic murmur is followed by the first sound or closure of the valve, which is more snappy because it is more tense and is shorter because the auricular systole being prolonged, auricular and ventricular diastole are closer, thus producing a more sudden relaxation of the mitral valve. Observers (16) have often noticed a short pause between the presystolic sound and the first sound of the heart in some cases of mitral stenosis. This takes place at that moment when the pressure of the ventricular systole is overcoming that of the auricular systole and the mitral valve which had been straightened at the time of the presystolic murmur, is thrown with its convexity toward the auricle, before the vibration of the first sound takes place. On the contrary, however, in those cases of mitral stenosis, where there is a failure of the auricular muscle, or where the stenotic opening is so small that but a small stream of blood can pass through or where the ventricle is failing, no crescendo presystolic murmur will be heard.

The same process takes place in aortic stenosis as in mitral stenosis, but to a lesser extent, because the valve and its ring are smaller. In this case, however, the equalization of the pressure of the contracting ventricle by the increase in pressure in the aorta causes a descrescendo continuation of the primary crescendo tone. In mitral stenosis the pause after the straightening of the valve or the first sound, follows the height of the crescendo.

A presystolic crescendo sound is also possible in any condition where pressure in the ventricle is increased sufficiently to make the mitral ring and its adjacent valve tenser during the end of auricular systole and beginning ventricular systole, so that the auriculoventricular valve is stretched, as is the case in aortic insufficiency where we find the Flint murmur. In other words, we have then produced a "relative mitral stenosis" because the pressure of the ventricle does not permit a complete opening of the mitral valve toward the end of auricular contraction. Flint (17) and Elsner (18) assert that this murmur is due to the regurgitant stream pressing upon part of the valve, but the pressure in an inclosed cavity such as the ventricle must be exerted equally on all parts of the ventricle, mitral ring and valves. The same condition may exist in adherent pericardium or ventricle hypertrophied from any cause (19). In these cases of socalled relative mitral stenosis the auricular muscle also hypertrophies as in true mitral stenosis.

A common finding is a systolic murmur over the aorta, which at postmortem shows very little or nothing pathological to explain it. This is found rather frequently in cases of high blood pressure with dilated aorta. Osler (20) speaks of this condition as a relative aortic stenosis, referring to the narrowing at the aortic ring. Here again we have physical conditions to produce a relative stenosis of the valves. The increased pressure in the aorta keeps the aortic ring tense. Upon the systole of the left ventricle, we have an increasing tension upon both sides of the valve, making it and its ring more and more tense. The stream of blood passing over the valve causes it to vibrate and produces the systolic murmur in similar fashion as the Flint murmur is produced at the mitral. A similar murmur, of course, may take place at the pulmonary valve, when pressure in the pulmonary artery is increased and is not uncommon where we also find a snappy second pulmonary sound. This murmur is by far more important than an accentuated second pulmonary for it shows a greater degree of backward pressure, but it is often misinterpreted as a transmitted mitral regurgitant murmur. It often precedes or accompanies a functional pulmonary insufficiency in a progressive mitral lesion.

Transient systolic murmurs or a louder murmur wherever a valve is already effected, may be heard when there is a temporary increase of pressure. Toward the end of systole of each heart cavity there is normally an increase of pressure on both sides of its distal valve. This pressure must necessarily stretch and make the ring and the valve tenser at that particular time. The stream of blood flowing over the valve segments must therefore cause this valve to vibrate. But the amplitude of the vibrations of these valves are not great enough to produce a sound loud enough to be audible to the human ear. When the pressure is however increased the strength of the entire process is increased so that it becomes audible to the human ear. Bridgeman (21) has found that there is normally a presystolic sound at the apex, which is below the range of human audibility. Morris and Friedlander (22) have shown how often a presystolic thrill is found where the heart's action is accelerated. A greater increase in pressure at the mitral, as we find in aortic insufficiency, amplifies the same murmur so that it can be very easily heard. In mitral stenosis we have the maximum effect, with its very marked presystolic murmur. Of course similar relations exist at all the valves and murmurs may be developed there in similar fashion. Transient murmurs due to increased pressure are often confused with hemic murmurs.

Socalled hemic murmurs at the apex in cases of atonic condition of the general musculature are due to relative insufficiencies of the mitral or tricuspid valves, and are caused by the lax papillary muscles permitting the closed funnel formed by these valves to become somewhat opened. The spiral muscular strands of the ventricles end in the papillary muscles so that a relaxation of these fibres would find greater expression at their free ends in the papillary muscles. The commonly accepted theory of a dilatation of the valvular ring is hardly tenable, because during systole the heart is contracting and its cavity must, therefore, be getting narrower. At the same time, the mitral being pushed toward the auricle, forms a funnel with its convexity toward and into the auricle. Both of these conditions tend to narrow the mitral ring and would prevent any dilatation of it. The pericardium too may be a factor in preventing any undue dilatation of the heart (23). In addition thereto in systole the muscle, forming a ring about the auriculoventricular valve, contracts, further narrowing it. Hemic murmurs are heard closer to the site of the valves because the less tense chordæ tendineæ do not transmit the sound as well and the lack of hypertrophy of the left ventricle does not bring it so close to the chest wall. There is also a possibility that most hemic murmurs originate in the right heart whose musculature is much weaker than that of the left side and more prone to relaxation. The rare hemic murmur which is diastolic can only be interpreted as a relative pulmonary insufficiency. The pulmonary ring in contradistinction to the aortic is easily dilatable (24).

Most authorities agree that the split second sound is due to the asynchronous closure of the semilunar valves. Since the closure of these valves depends upon the pressure within the aorta and pulmonary artery, we can expect to find a split sound where either vessel is called upon to carry a greater pressure and this is often found to be the case clinically. At the apex a split first sound is quite common and since, as we have assumed, the first sound is due to the auriculoventricular valves, these, as in the case of the semilunars, must close asynchronously. This is possible when either ventricle is called upon to exert a greater pressure upon its auriculoventricular valves, closing them a fraction of a second sooner than the other auriculoventricular valves. It is not possible for any valve to be forced to close and relax so quickly as to be reduplicated or that the ventricle could contract and relax so quickly as is explained by some. Split murmurs occur in acute changes of pressure in the various heart cavities and vessels before comparative equalization and synchronization takes place.

CONCLUSIONS.

1. That the most common intracardiac sounds are caused by the vibrations of some valve, with the exception of the first heart sound in which the chordæ tendineæ may play a greater part.
2. That the third heart sound is due to the vibration of constricting pulmonary veins set into motion by the regurgitating blood of auricular contraction.
3. That murmurs of insufficiencies are caused by the vibration of a tense valve set into motion by the regurgitating blood.
4. That the presystolic crescendo murmur of mitral stenosis or Flint murmur is developed by the vibration of the mitral brought to a stretch by the beginning contraction of the ventricle before auricular contraction has ceased.
5. That relative stenoses at aortic or pulmonary valves are produced when there is an increase of pressure in aorta or pulmonary artery.

6. That hemic murmurs are due to valves insufficient because of lax papillary muscles.
7. That reduplicated sounds at both base and apex are due to asynchronous closure of the valves.
8. That this conception of the factors concerned in the production of heart sounds and murmurs, seems to simplify the understanding of the function of the heart. It offers an adequate physical explanation of conditions hitherto not understood.

Cardiospasm Associated with Esophageal Diverticula

By PORTER P. VINSON, M.D.,
Rochester, Minnesota.

Diverticula of the middle portion of the esophagus have been observed rather often at postmortem, but rarely have been demonstrated during life. They occur usually in the region of the left bronchus, and are due to healing processes following inflammatory lesions in the periesophageal glands. However, Le Count and Brosch have reported small diverticula of the thoracic esophagus apparently not caused by inflammatory reactions, but by lack of support of the esophageal wall. The contraction of fibrous tissue pulls a small portion of the esophageal wall outward and upward, and produces the socalled traction diverticula. The apices of such diverticula point upward, so that there is no tendency for ingested food and fluid to accumulate in them and increase their size, as is the case in pulsion diverticula.

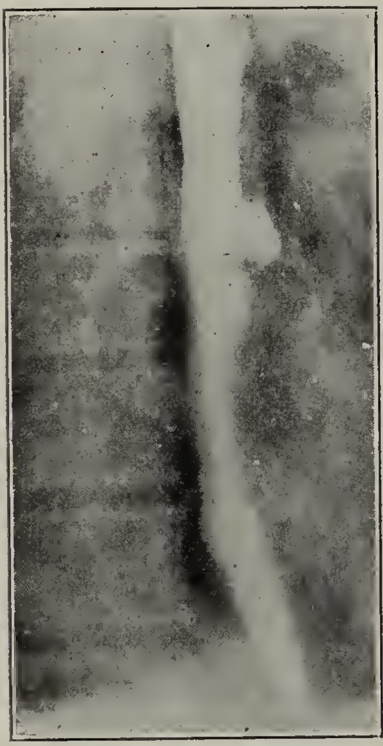

Fig. 1 (Case A392496).—Cardiospasm with slight dilation of the esophagus associated with small diverticulum.

During the past nine months two patients with symptoms and findings typical of cardiospasm have been seen in the Mayo Clinic, in whom a pouching of the left side of the middle of the esophagus was found beside obstruction at the cardia.

Case I (A392496).—W. J. S., a man aged forty-nine years, had had difficulty in swallowing for ten years. The onset of the symptoms had begun with sudden obstruction to food with regurgitation, and inability to swallow either liquids or solids for twenty-four hours. Since that time there had been constant dysphagia with short periods of complete closure. The food seemed to stick in the lower esophagus, and he had had to swallow several times with each bolus before it would pass into the stomach. If it failed to pass it was regurgitated.

Röntgenographic examination revealed obstruction of the barium meal at the cardia with slight dilatation of the esophagus, and a small diverticulum that projected from the left side of the middle portion (Fig. 1). A 45 F sound was passed into the stomach without obstruction, and following this simple treatment, the patient was completely relieved from dysphagia. It is probable that dilatation of the cardia with a hydrostatic dilator will be necessary in order to give permanent relief.

Case II (A417430).—J. E. S., a woman aged forty-seven years, fourteen years before coming to the clinic had noted occasional obstruction of food at the cardia associated with slight epigastric pain. The obstruction increased gradually, but the chief complaint was of pain which had become very severe, radiating to the back and over the left side of the chest. The attacks of pain bore no relation to the time of taking food. The patient said that she was never able to sit down and eat her meals, but was obliged to walk around the room while forcing food into the stomach. As much difficulty was experienced with liquid as with solid food. None of the food had ever been regurgitated.

A röntgenogram revealed an obstruction at the cardia with marked dilatation of the esophagus, and a large diverticulum arising from the left side of the middle portion of the tube (Fig. 2). The cardia was dilated to 28 feet of water pressure with complete relief from dysphagia and pain. Subsequent röntgenograms revealed very slight lagging of the barium meal at the cardia; the diverticulum remained unchanged.

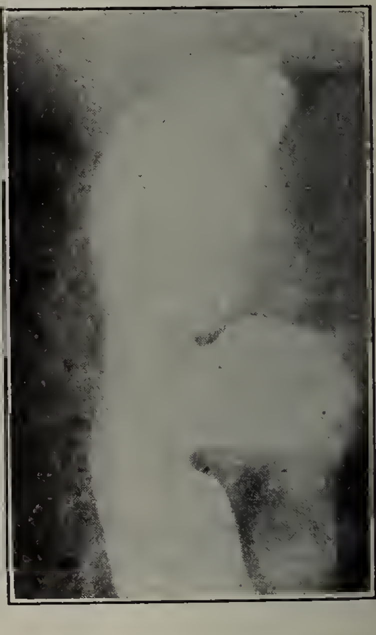

Fig. 2 (Case A417430).—Cardiospasm with marked dilation of the esophagus associated with large diverticulum.

The mechanism of the formation of these diverticula is, of course, purely speculative. They may have resulted from congenital weakness of the esophageal wall, or they may have had their origin in tiny traction diverticula. In either case they could not have attained considerable size without the spasm at the cardia causing retention in the esophagus, and adding the pulsion force necessary to increase the size of the pouch. It is interesting that neither of the patients had symptoms suggesting that the diverticulum was a factor in the production of the dysphagia. It is possible that the second patient will have food obstruction from the diverticulum at some future time, but if this occurs, food can be given through a stomach tube which has been guided beyond the sacculation on a previously swallowed silk thread.

The Circulatory System in Tuberculosis*

By F. M. POTTENGER, A.M., M.D., LL.D., F.A.C.P.,
Monrovia, California.

In order to understand how the circulatory system is affected in tuberculosis it is necessary, first, to understand normal conditions, and second, to understand what there is in tuberculosis which disturbs this normal action. The circulatory system provides the water for the body cells: 1, in which they live; 2, from which they take up the substances which are necessary to their life and activity, and 3, into which they give off products which have a regulatory effect upon the organism and deleterious products which result from their activity.

The body cells are capable of taking up and giving off water. This water content is subject to change from time to time under varying conditions, which depend upon their acid base balance. This varies with many pathological states which are met in practice, such as toxemia, anaphylaxis, asphyxia, and anesthesia. Any change either toward greater or lesser alkalinity on their part increases their water absorbing power and correspondingly decreases the relative amount of free water in the tissues. The amount of water that can be absorbed beyond the normal, as given by Fischer (1) is surprising. He says that even the difference in absorption of water by the red and white corpuscles in venous blood under the influence of carbonic acid concentration as compared with arterial blood amounts to from five to fifteen per cent.

Any marked variation in water content is accompanied by corresponding variation in function, but just what effect this exerts upon the individual we do not yet fully understand. A slight variation in the acid base balance of the cells in the nature of an increased acid content is expressed as fatigue; a marked variation is at least accompanied by such gross disturbance in physiological balance as is represented by malaise, lack of endurance, loss of strength, loss of appetite, digestive disturbance, aching, rise of temperature, and, if the brain cells are involved, delirium and coma. Therefore, it should be a part of clinical study to determine what factors disturb the acid base balance of the body cells and the free water balance of the body, and what part they play in the production of symptoms.

The heart and bloodvessels form the system which keeps the body cells supplied with water, and if the cells are to work to best advantage this function must be carried on regardless of the changes which occur in the water containing power of the body cells themselves and regardless of the amount of free water in the body. It will be readily understood that anything which disturbs the acid base balance of the cells and changes the amount of free water in the body or reduces the functioning power of the heart or alters the texture, elasticity or size of the vessels, will interfere with the efficiency of the circulation. In tuberculosis there are conditions which are inimical to circulatory equilibrium, which produce their effects in each of these ways.

In discussing a disease with so many and so varied manifestations as tuberculosis, it is necessary to make plain that it causes changes in the organism which vary from disturbances in equilibrium scarcely perceptible to those which impair the action of every system. It is further necessary to realize that the circulatory disturbances will vary accordingly.

Tuberculosis is an infectious disease and when active gives origin to toxins which gain access to the blood stream and produce their deleterious effects on the body as a whole. Toxins show a particular affinity for the nervous system and through their action on the vegetative system affect every tissue of the body. One effect of toxic action is to make the tissues more acid. As a result of this they bind more than the normal amount of water, and are disturbed in the normal performance of their function. The heart and bloodvessels bear their share of this injury. Not only is the amount of free water reduced by this reduction in normal alkalinity, but, if the reduction be very marked, the function of the cells is disturbed and existence of the body as a living unit is threatened.

Conditions are often met in tuberculosis, particularly in the advanced phases of the disease, in which circulatory efficiency is disturbed by alterations in the character of the circulatory fluid and in the efficiency of action of the body cells themselves. All changes of this kind throw extra burdens upon the circulatory apparatus at a time when the efficiency of the heart and vessels is reduced because of other handicaps which will be mentioned later.

The mechanism of the circulatory apparatus is interfered with in many ways which are evident to clinical observers. In discussing the competency of the heart and bloodvesesls to meet the circulatory needs in tuberculosis, we have very different conditions to describe in early and in late tuberculosis. At first the heart is fully competent to cope with all factors which interfere with it. The toxic effects are slight and whatever reflex disturbances are present are unable to make serious impression; consequently, except under undue stress, the heart is able to maintain its physiological balance. In more advanced tuberculosis, the physiological reserve is used up and the heart functionates at a disadvantage.

The heart undergoes degenerative changes as toxemia becomes chronic; and the patient approaches an extensive disease which is accompanied by many conditions which call for increased circulatory demands, with a heart which has been deprived of more or less of its reserve strength.

Toxins act upon the nervous and endocrine systems as a whole but cause peripheral effects which are expressive of stimulation of the sympathetic nerves and sympathicotropic glands of internal secretion. This tends to accelerate the heart action and to disturb the vasomotor equilibrium.

Pulmonary tuberculosis and pleurisy both reduce the mechanical action of the diaphragm. The diaphragm is the most important muscle of respiration. It has a pistonlike action and when it contracts (descends) it enlarges the thoracic and reduces the abdominal area. The effect of this is to dilate the lungs and the right auricle thus favoring the ingress of air to the lungs and blood to the heart. At the same time there is also an active force exerted upon the great blood containing reservoirs of the abdomen by the compressing action of the diaphragm, by means of which the blood is literally squeezed out, as described by Wenckebach, (2) like water from a sponge. This aspiration of blood into the right heart by the inspiratory act is one of the important extracardiac mechanisms by which the circulation is maintained.

---

*Read before the Twenty-Third Annual Meeting of the American Therapeutic Society, Washington, D. C., May 2, 1922.

Decrease in the inspiratory act is recognizable in very early cases of pulmonary tuberculosis, because the strong crura of the diaphragm are innervated by the phrenic nerves and through them are thrown into spasm when the pulmonary parenchyma is inflamed. In advanced cases this effect is more marked and more easily recognized. In many cases of pulmonary tuberculosis, pleural adhesions, particularly at the base, are also present as another factor in producing the same effect. The lesion in the lung itself by decreasing the elasticity of the tissue also reduces the normal inspiratory excursion.

As a result of all of these factors the blood pressure is low, the arteries of the body are relatively empty, and the veins are relatively full. Most patients who are even moderately advanced in the disease show some cyanosis. In many cases of far advanced tuberculosis large areas of pulmonary vessels are obliterated. One would naturally think that this would throw a tremendous overload on the heart and, in fact, that has been the teaching; but experiments have been performed on animals in which one half of the pulmonary area has been removed without showing any lowering of the systemic blood pressure. The remaining vessels dilated to such an extent that the circulation was carried on with no recognized embarrassment. It is also a common experience today in inducing artificial pneumothorax to collapse an entire lung. This may be done without producing any serious circulatory embarrassment. While these facts show that the heart is able to withstand whatever extra burden is thrown upon it by this procedure, yet it would not be safe to advance them as arguments to prove that no extra load is thrown on the heart by destroying large areas of pulmonary vessels. These observations must be interpreted rather as showing that, in instances where no untoward effects appear, the heart is able to carry on its function in spite of the decrease in vascular area.

The heart performs its function best when lying freely in the pericardium in its normal bed between the two lungs; however, if any considerable amount of lung tissue is destroyed in one lung, either by cavity formation or fibrous changes, that lung contracts and becomes smaller. The opposite lung takes upon itself a state of compensatory enlargement. The result is that the heart is disturbed in its relationships to the surrounding tissue. The contracting lung often withdraws that portion which is normally interposed between the heart and the chest wall and the enlarging lung on the other hand increases correspondingly in volume that portion of its tissue which lies between the heart and the chest wall.

Another condition which militates against its normal working is the shifting of the heart to the right or to the left with the pathological changes which occur in the pulmonary tissue. Sometimes the heart, following a contracted right lung, will shift entirely to the right of the median line, and more often following a contracted left lung will shift to the left. In some cases the entire organ lies considerably beyond the left border of the sternum. As the heart shifts its position it is compelled to functionate at a corresponding disadvantage.

Pleuropericardial adhesions also interpose obstacles to normal action. In instances where the heart is markedly shifted to one or the other side the pericardial space is encroached upon since the sac cannot move *in toto* because of its attachments. Instead of having the heart moving freely and unrestrictedly in the pericardial sac, we have it pushed over to one or the other side of the pericardium while the other is encroached upon by the compensatorily enlarged lung. In other instances we find an adherent pericardium which embarrasses the heart in its rhythmical contraction and expansion.

In pulmonary tuberculosis the innervation of the heart and its endocrine control too are disturbed. During toxemia the action of the sympathetic nerves and such sympathicotropic internal secretions as that from the adrenal body and the thyroid increase the tendency to accelerate the heart beat. This is also favored by the shifting of the acid base balance (acidosis) which results from the toxins as well as many other causes. On the other hand, the pulmonary vagus of the parasympathetic system is stimulated and sends reflex impulses to the heart which attempt to slow the contractions. The resultant rate depends upon the relative strength of these opposing stimuli.

In this brief discussion I have attempted to show a few of the complex factors which are operating to disturb the normal circulatory efficiency in pulmonary tuberculosis and from this we may draw conclusions how to aid the circulatory mechanism in its service to the organism during the time that the body is combatting the disease. It is evident from this description that there is practically no therapeutic problem as far as the heart is concerned in early clinical tuberculosis, but that the problem grows and becomes a serious one as the disease advances with its prolonged toxic action and its tissue destruction. When we say, then, that early tuberculosis is practically always curable, the cure of the patient at this favorable time should be the answer to the heart problem. But it will not be, for cases of advanced tuberculosis will continue to be found which we as physicians will be called upon to treat.

The particular group of symptoms which destroy the tuberculous patient are those which are due to the toxins. As a part of the general action of toxins there is a disturbance in integrity and functional activity of all body cells. The heart and bloodvessels share this injury and it is probable that this proves to be the one greatest factor in interfering with the normal working of the circulatory mechanism. It is reinforced, however, by many others which increase its difficulties.

Therapeutic measures in advanced tuberculosis should be directed first toward warding off toxic effects and second toward improving circulatory efficiency when it is disturbed. Needless to say rest is the most effective of all measures of relief which can be directed toward the heart. This is evident from the fact that it requires six to eight times as much blood for muscles in action as it does for muscles at rest, and that the lungs are called upon to furnish six to eight times as much oxygen to provide the increased energy. Translating heart contractions into terms of work the heart does an amount of work daily equivalent to raising a ton weight one hundred and twenty-two feet. Exercise increases this and active tuberculosis interferes with the normal circulatory mechanism and forces the heart to work at a disadvantage. When the disease is active rest should always be prescribed for safeguarding the heart as well as for its beneficial effect upon the disease as a whole.

Since the main heart condition met in tuberculosis which is directly traceable to the disease is of the degenerative type there is little in the way of therapy that can be applied when once the organ begins to show signs of weakening. Strain upon the heart muscle usually manifests itself by vague symptoms. The patient begins to show signs of nervousness, irritability, anxiety, insomnia, lagging appetite, and usually disturbed digestion. Rarely is pain present, although it may be at times. This condition should be met by rest, mental and physical. Bromides and opiates will aid in bringing about both, although the latter should be discontinued as soon as the critical condition is past.

Digitalis in large doses, twenty to thirty drops of tincture three times a day, should be administered for its effect in slowing and strengthening the contraction and thus favoring the filling of the coronary arteries and improving the heart's nutrition. Digitalis should not be given in small doses, but in sufficient amount to produce slowing of the pulse or nausea within a very short time. Intravenous preparations are even better than those given by the mouth. If the heart passes the crisis digitalis should be kept up for some time. I usually give it for a few days, then discontinue for a few days and resume again. Little help should be expected, however, when frank dilatation comes on as a result of the disease, for then therapeutic measures are too late. The heart has fought its battle and lost.

One must always bear in mind that conditions of toxemia are accompanied by an increase in acid radicles in the body cells and a decrease in free water in the body. While the degree of acidosis may not be severe, yet, lasting as it is apt to do over a long period of time, it produces its deleterious effect upon the organism as a whole. It may be combated by the administration of alkalies. It is my custom to combat this condition by the use of bicarbonate of sodium. I administer about ninety grains a day for a period of several weeks, then discontinue for a week or two and resume again. It should be accompanied by large quantities of water, so as to keep an ample free water supply for the body cells. Or it may be used by the Murphy drip, employing a three per cent. solution and continuing three to four hours a day for two or three weeks or more at a time.

The Use of Digitalis in Hearts with Regular Rhythm

By LESLIE T. GAGER, M.D.,
New York,
Instructor in Medicine, Cornell University Medical College; Assistant Physician, Cardiac Clinic, New York Hospital.

So large a share of attention has been drawn to auricular fibrillation, especially since the therapeutic possibility of its restoration to sinus control has been shown, that there is a tendency to slight a field of even greater importance, namely, the treatment of the regular heart which begins to show the signs or symptoms of insufficiency. For in those patients, whose damaged hearts still maintain normal sinus rhythm, the efficient use of digitalis affords the double opportunity of promptly relieving distress and disability and preventing or indefinitely postponing the graver events in the progress of heart disease. Here, in these hearts with regular rhythm, the recognition of decompensation, however mild, is as much to be desired as the early detection of glycosuria in diabetes, with the end in view in either case of enabling a vital organ to do what work it can with the least strain.

Nevertheless, as Mackenzie has pointed out, too little attention continues to be paid to early heart failure; and in all degrees of cardiac insufficiency, and more particularly when the rhythm is still regular, it remains only too commonly true that the small doses usually given fall short of the digitalis effectiveness that should be and can be obtained. The importance of proper digitalization, then, in the face of the so frequent abuse or even omission of digitalis, is a subject that warrants repeated emphasis.

Ambulant patients encountered in office practice and in the cardiac clinic provide typical instances of the relief from digitalis therapy that may be obtained in both mild and more advanced states of insufficiency.

CASE I.—B. W., aged twenty-seven years, married, an actress, sought treatment of a throat specialist because of a catarrhal condition that was interfering with her singing, and was referred by Dr. I. W.

Voorhees because of her history and heart murmur. The family history was irrelevant. At nine years of age she had had an attack of acute rheumatic fever, and was kept in bed for one year. At ten, her tonsils were removed, incompletely. When she was fourteen years old there was a second illness, of six weeks' duration, with acute rheumatic fever, and at twenty-three years a third attack, following which the patient was told she had a weak heart and was kept at rest for five months. Her tonsils were taken out completely at this time. For the last four years she had suffered fever from slight dyspnea on exertion. The bowels had been constantly irregular. Following removal of the ovaries at nineteen, menstruation ceased and there was a period of nervousness.

After a summer at rest in the country, during which her weight went up to 114 pounds, the patient returned to her work, which required considerable exertion for a half hour period twice a day. In two months her weight fell to 105 pounds. Her breathlessness increased, and for two weeks she had had to use two pillows at night. There had been no cough, no swelling of the ankles. For a week there had been a full feeling in the precordial area, and palpitation. She was suffering from sleeplessness. She drank a cup of coffee every morning and every evening; she did not smoke. Her appetite was poor.

Physical examination revealed a woman slightly underweight, with pallor of the mucous membranes. The pupils reacted normally, the teeth were in good repair, the tonsillar beds were clean and the lungs were clear. The heart was slightly enlarged, relative dulness extending 8.5 cm. to the left in the fifth interspace and three cm. to the right in the third interspace. Though the chest wall was thin, the impulse was slightly overactive. There was a blowing systolic murmur at the apex, partly replacing the first sound and transmitted into the axilla. There was no evidence of stenosis, even after exertion and change of position. The second pulmonic sound was accentuated. The apex and radial rates were 80 a minutes, regular in rhythm. The blood pressure was 115/70. There was no enlargement or tenderness of the liver, no edema.

A condition of rheumatic heart disease with mitral insufficiency was obvious, but the examination was not nearly as good evidence of an incompetent heart as the history of increasing dyspnea and fatigue. Therefore tincture of digitalis was prescribed according to a schedule that brought the total to 210 minims, the approximate tolerance for her weight, thirty-six hours after her visit, following which one daily dose of thirty minims was to be taken. The temptation to prescribe a sedative was resisted. When the patient returned on the sixth day, she was able to report that her shortness of breath was gone, that she was sleeping all night on one pillow, and that the palpitation and fullness had disappeared. Her pulse rate was 68 and regular. She had had no nausea. The daily dose was diminished to twenty minims, and on this she has been keeping her engagements without further trouble. Under observation, entire withdrawal of the digitalis may be possible.

Case II.—This patient, D. W., aged thirty-nine years of age, married and the mother of three children, is an example of more serious heart disease. She was sent to the Cardiac Clinic of the New York Hospital on August 31, 1922, because of increasing shortness of breath and swelling of the legs. Her family history was unimportant. In childhood she had had inflammatory rheumatism and she gave a definite history of another attack in 1918, since which time she had noticed shortness of breath and some swelling of the ankles. She went through her pregnancies without complications, but for several years had suffered from typical gallbladder attacks. She was admitted to the first surgical division of the New York Hospital on June 20th, and the diagnosis of chronic cholecystitis and cholelithiasis was confirmed at operation by Dr. C. E. Farr. She had a definite mitral stenosis and insufficiency. The Wassermann test was negative. She was discharged, after an uneventful postoperative course, on July 12th, to go to the country for convalescence. The patient received no digitalis during her hospital stay. In the country, a hoarseness, which the patient said later she had noticed soon after the operation, became marked, and finally she was advised to go back to the city for throat treatment. Since July 15th, she had been sleeping on three pillows and had had a cough and had lost her voice entirely for a week.

Physical examination showed a woman of good nutrition, weight 140 pounds, with moderate cyanosis and dyspnea, and slight distention of the large veins of the neck. She was unable to speak above a whisper. The upper air passages were negative. There were moist râles at the bases of the lungs. A forceful impulse was present in the fourth and fifth interspaces in the left nipple line and relative cardiac dullness extended ten cm. to the left and 3.5 cm. to the right. No definite widening of retromanubrial dullness was made out. The murmurs of mitral stenosis and insufficiency were outspoken and the regular rhythm was interrupted by twelve to sixteen premature beats a minute, many of which were frustate contractions, the apex rate being 96, the radial 84. The liver was not swollen. There was a slight pitting in the pretibial regions.

The diagnosis of left recurrent laryngeal paralysis was confirmed the next day on consultation, by Dr. J. P. Erskine. A six foot plate showed considerable enlargement of the cardiac shadow, with the shadow of the left pulmonary vein prominent. The electrocardiogram showed large P waves as evidence of auricular hypertrophy and many auricular premature beats. Digitalization was begun immediately, 120 minims of the tincture being given the first night, and forty minims twice a day for the next two days, so that the patient reached her calculated tolerance forty-eight hours after the course was begun. Thereafter, twenty minims twice a day was ordered. On her return to the clinic on September 7th, the pulse rate was 80, there was no deficit, and only occasional premature beats. Dyspnea and cough were less and there was slight return of the spoken voice. Continuing digitalis, twenty minims twice a day, on September 14th the voice was nearly normal, and cough had disappeared. On September 21st, the voice was unimpaired. The rhythm was entirely regular at the last two visits.

Unfortunately for the patient, she felt so well that she broke two rules: she became intermittent in her use of the digitalis and she did some heavy lifting.

Two days later, on November 2nd, she had to be admitted to the hospital, displaying much cyanosis and dyspnea and a rapid laboring heart. Her voice was somewhat hoarse on the day of admission but with rest in bed and digitalis this vanished and her improvement was rapid. During the next six months under digitalis she continued in good condition.

What has been said of the treatment, and the results of treatment, of the two patients, taken as types of mild and of more serious decompensation, is true of the majority of hearts, which, though still regular in rhythm, have depleted their reserve and are manifesting their inability to carry their loads by overactivity, dilatation, various degrees of passive congestion, and the attendant symptoms. It is the rule that, irrespective of the cause of cardiac disease, digitalis may be expected to exert its influence through bringing about increased power of contraction and control of rate, though it is obvious that a myocardium, the seat of longstanding disease and degeneration, cannot be restored to the function which was possible earlier in the disease process. Now if decompensation progresses, the common termination is the condition of which Lewis has said, "There is no ailment in which such success can be achieved, no other cardiac disorder which may be so speedily benefitted as the well managed case of auricular fibrillation. . . . As a direct result of active treatment the moribund may be restored and many years be added to their lives." But it can be as confidently asserted that active digitalis treatment may do as much for the regular heart, along, of course, with the fundamentals of rest, diet, care of infection, and the rest. Indeed, not only may the failing organ be restored to efficiency, but it is quite possible that the onset of auricular fibrillation may be postponed or prevented. The subsidence of the auricular premature beats in our second patient suggests such a happy result. It will not be gainsaid that it is more desirable to avert fibrillation by digitalis early, than to restore it later to sinus rhythm, in half the cases, and impermanently, by quinidine.

If there can be no question as to the benefits of efficient digitalis therapy, the essential points are to know when and how digitalization is to be carried out. The indications in the regular heart vary from the slight dyspnea, rapid and increased heart action, easy fatigue and mental distress of mild insufficiency, to the cases with extensive edema and other signs of passive congestion. Occasionally only one frank sign or symptom will be present, as in the instance of a man with complete heart block, for whom, without slowing of an already irreducible ventricular rate, a full course of digitalis brought pronounced relief from dyspnea. Undoubtedly rest in bed alone would benefit many of these patients, but in general we are dealing with individuals who must be ambulant.

While much digitalis is given where it is not needed, the greatest abuse in its use continues to be that it is given in doses that are not effective because they never catch up with the rate of elimination. It becomes a problem in arithmetic: if ten drops are given three times a day, and two drops equal a minim, and elimination is at the rate of twenty minims a day, when will digitalis effect be secured? Yet nothing more clear and concise has ever been said of what is required of digitalis than Withering's words 140 years ago: "Let the medicine be continued until it either acts on the kidneys, the stomach, the pulse or the bowels; let it be stopped upon the first appearance of any one of these effects." To these, the effect on the respiration has been added by Christian.

The administration of digitalis, at the outset of treatment, by the large dose method should supplant the small doses, though the latter remains preferable when an uncertain amount of digitalis has been recently given and when there ensues, under digitalis, increasing frequency of premature beats, a condition which is manifestly difficult to ascertain in ambulant patients, but is apparently very rarely serious, if one may judge from the absence of such consequences, as ventricular fibrillation. From his hospital experience, Christian has stated that an instance of harm from digitalis given by the outside physician has never come to his attention. For the large dose method, there are two important facts to be known: the patient's weight and the strength of the digitalis preparation. The working rule with a good tincture is to give two minims to the pound of body weight to obtain full digitalization. This approximates the amount required when the digitalis is so standardized that one hundred mg. of leaf is equivalent to the cat unit, 0.15 cat unit being required to the pound for the patient. Thus for a man of 150 pounds, the theoretical dose of tincture is 22.25 c.c. of tincture, or 330 minims, in comparison with 300 minims by the rough calculation. The schedule of administration of the total may be varied, but in general, one half of the calculated amount may be given at the first dose, one fourth six hours later, an eighth of the total amount at the end of the second six hours, and then in tenths of the total dose until the effect is secured. For people at work, a twelve hour schedule in often more convenient, and later, a single daily dose is as effective as the same amount divided.

The measuring of the doses is obviously important—one convenient way of insuring accuracy is by using the cubic centimetre graduate (one c. c. equals fifteen minims) and another is by diluting the tincture so that a teaspoonful dose equals ten, twenty, or thirty minims as desired. The powdered leaf (one grain equals ten minims) in the form of tablets is also an accurate method and sometimes will be taken when the patient cannot retain the tincture.

SUMMARY.

The value of digitalis in hearts with normal sinus rhythm is discussed, with illustrations of its effect in both mild and marked cardiac insufficiency. Compensation is restored, with prompt relief of symptoms. The more serious consequences of heart failure may be prevented. Thus, the disappearence of numerous auricular premature contractions under digitalis would suggest the checking of a process that might (there is no basis of proof) go on to auricular fibrillation.

Full digitalis effect, it is emphasized, is essential for securing maximum therapeutic benefits, in which respect much of the current use of digitalis falls short of what is easily possible.

Practical considerations in digitalis administration are presented.

Heart Disease in Relation to Marriage and Pregnancy

By W. W. HERRICK, M.D.,
New York.

HEART DISEASE AND MARRIAGE.

Every practitioner of medicine is asked the question, Should a woman with heart disease marry? No general answer to this question can be given, each case having to be decided on its own merits. If the patient has an aortic insufficiency the physician must remember that syphilis may be the underlying cause. The same is true of patients of childbearing age with anginal pain or general myocardial insufficiency without obvious valvular lesion. Such subjects having a definite syphilitic background should not marry. In the first place, their expectation of life is very short, as a rule not more than three years. Again, there is danger of the transmission of the underlying disease, to the offspring. Decision in the more ordinary forms of heart disease, which are the result of rheumatic fever, scarlatina, or other infections, is a less simple matter. The economic side of the question is not unimportant. If marriage brings increasing anxieties and added physical burdens to a patient who is barely holding her own in the protection of her own home, the venture is probably unwise. On the other hand, if marriage is to bring added comfort and less of effort to the cardiac patient, the opposite view might be taken in the individual case. In general, patients who have suffered a break in compensation and who, within two years, have been confined in bed because of dyspnea, edema, anginal pain or attacks of pulmonary edema, should avoid the added burdens of matrimony. In making a decision, the physician has four kinds of evidence to consider: 1, symptoms; 2, physical signs; 3, exercise tolerance and other functional tests, and, 4, kind of lesion.

Symptoms.—Patients presenting dyspnea on ordinary effort, persistent cough due to chronic pulmonary congestion, attacks of acute pulmonary edema—often wrongly called cardiac asthma—true anginal pain, or swelling of the feet, should in general avoid matrimony.

Physical signs.—Enlargement of the heart, either from dilatation of hypertrophy or both; rapid pulse rate at rest; evidence of a serious valvular defect, either insufficiency or stenosis; evidence of myocardial weakness, such as *pulsus alternans;* persistent arterial hypertension particularly a high diastolic pressure; these are the most important contraindications to be taken into account.

Functional tests.—These are notoriously inexact and subject to the play of a number of factors outside the myocardium. However, they have some value. Of these the simplest and probably the most reliable is the socalled exercise tolerance test. After an exercise which makes some demand on the individual, the pulse rate should not be unduly accelerated and should, within two minutes after completing the exercise, return almost or quite to the previous rate at rest. If the pulse rate remains rapid and if the shortness of breath is pronounced, a valuable hint is given that the condition of the myocardium is unsatisfactory. The exercises which may be used may vary from a hundred hops in a vigorous individual to a few flexions of the arms in one suspected of myocardial weakness. A very good standard exercise is raising a ten pound dumb-bell at arm's length above the head from ten to thirty times. The vital capacity varies, in general, inversely as the cardiac capacity, and has some value as a test for cardiac efficiency.

The kind of lesion.—Experience has shown that individuals with mitral stenosis bear labor less well than those having other valvular lesions. One should, therefore, hesitate to sanction marriage and pregnancy when there is evidence of great narrowing of the mitral valve, as shown by marked cyanosis, cough, shortness of breath on effort, and a diastolic presystolic murmur occupying the entire diastolic period. Patients with marked aortic insufficiency, especially when the pulse pressure is high and evidence of dilatation of the left ventricle is present, should not undertake increased burdens. Patients with mitral insufficiency with slight or moderate mitral stenosis without evidence of myocardial weakness can in general be favorably considered. Auricular fibrillation when it occurs before middle life is ordinarily a sequel of mitral stenosis or mitral insufficiency and should, as a rule, interdict matrimony. There are, however, exceptional cases of auricular fibrillation in which cardiac functional efficiency is satisfactory and in which this disturbance might be disregarded.

Decision in general must depend upon careful weighing of symptoms, physical signs, exercise tolerance, and the diagnosis of the individual lesion.

PREGNANCY AND HEART DISEASE.

It is important for the medical man to recognize the general truth of the dictum, "Women with chronic cardiac disease bear matrimony and pregnancy well." The practitioner should therefore be very sure of his ground before advising adversely in the question of marriage and pregnancy, and the factors enumerated above on marriage and heart disease should be taken into account. In the event of pregnancy occurring in the woman with chronic heart disease, it should be remembered that in the average case pregnancy and labor will proceed with little difficulty and that it is only in the exceptional case a serious situation arises. Nothing is more unfair than to raise an alarm or advise immediate termination of pregnancy just because a heart lesion is discovered. Most patients can be kept from a cardiac breakdown and brought to term and to delivery with entire safety.

The first endeavor of the physician should be to prevent cardiac decompensation during pregnancy. This can usually be done by recognition of the heart lesion early in pregnancy, by frequent observation, and by prompt treatment at the earliest sign of decompensation. So soon as the pregnant cardiac patient shows unusual shortness of breath, cyanosis, weakness, or edema, she should be kept at rest, either in bed or in a chair and treated, not as a pregnant woman, but as a case of decompensated heart disease. In general, in such a case the patient should have a limited allowance of fluid, enough digitalis to give satisfactory physiological action, diuretics and sedatives as indicated. Upon such a regimen intelligently carried out compensation is usually restored and the patient can continue the pregnancy under careful supervision. During pregnancy the cardiac patient may require frequent periods of treatment of the kind outlined in order to preserve the balance of the circulation and ward off decompensation. If decompensation occurs early in pregnancy, before the fourth month, and without special strain to cause it, it is usually unwise to continue the pregnancy. If decompensation occurs after the fourth month and responds well to treatment, it is in general safe to allow the patient to proceed with the pregnancy if she has expert oversight. If at any stage of the pregnancy the compensation is not at least partially restored by treatment, necessity for action is at once apparent.

In general, one should not take any measure to deliver a patient with decompensation until medical treatment has been tried. The double burden of decompensation and *accouchement forcé* is one which is badly borne. Most of the deaths reported in pregnancy with heart disease are due to unwise interference when serious decompensation exists. If a certain measure of compensation is restored by medical measures a satisfactory outcome of an induced labor is much more likely to occur.

If a serious cardiac breakdown can be averted by medical treatment, it is usually wiser to allow the cardiac patient to go on to term than to accelerate delivery by interference. In most cardiac cases the patients will go through labor normally with little difficulty. It is important that the heart be under control of digitalis at the time of labor and that all possible strain be avoided. The first stage of labor places no great burden on the circulation. It is the second stage with its play of the voluntary muscles and the entire mechanism of expulsion that is a severe strain to the compromised heart. This second stage, therefore, should be made as short and as easy as possible by appropriate obstetrical methods. If anesthesia is required, ether is probably the most satisfactory, as it is borne very well by cardiac patients. If obstetrical conditions do not promise a normal labor, Cæsarean section may be considered. This is rarely necessary but is borne well by the cardiac patient. In experienced hands it is preferable to a prolonged labor from a narrow pelvis or other obstetrical obstacle. It is often preferable to *accouchement forcé* in advance of term.

The question of sterilization of the cardiac patient is not unimportant. If pregnancy and labor have been a severe strain to the heart and any degree of decompensation has occurred this operation is to be looked upon with favor. One advantage of delivery by Cæsarean section is the opportunity this furnishes to render the patient immune from further childbearing.

All danger is not at end with the delivery of the child. Acute cardiac decompensation may occur immediately after delivery or may be delayed several days. In patients with mitral stenosis, acute pulmonary edema is prone to occur after delivery. The patient must be kept very quiet. If acute pulmonary edema should occur during delivery, the loss of considerable blood from the uterus should be encouraged; if, at a later time, prompt venesection, providing the patient is not anemic, is effective. Morphine and digitalis, as indicated, should also be used. The exercise tolerance test may be used as a rough means to govern the amount of activity allowed the convalescing patient. If the response to effort is satisfactory, the patient may be allowed out of bed and may gradually resume such pursuits as are within the capacity of the heart.

THE PERMANENT EFFECT OF PREGNANCY ON A DISEASED HEART.

In patients who have been carefully supervised and prevented from serious cardiac breakdown during pregnancy, there should be little or no decline in cardiac reserve power as the result of the performance of this function. Three or four months after delivery in many of these cases no decline in exercise tolerance can be made out. On general principles, however, it is unwise to subject the woman with serious heart disease to the strain of repeated pregnancies. If the patient has one or more healthy children, the question of sterilization is one to be considered seriously. Aware of the tendency of ordinary heart disease to become more serious as time goes on, the matter of sterilization with these patients is one of great importance. One of the reasons for advising Cæsarean section in selected cases is the ease with which sterilization can be accomplished at that operation.

SUMMARY.

The important points in the management of pregnancy and heart disease may be summarized.

1. Careful antenatal supervision is imperative.
2. All patients showing signs of decompensation at any period of pregnancy should have medical treatment, preferably in a hospital.
3. The response to medical treatment of the average case of chronic valvular disease of the heart in pregnancy is satisfactory and the same principles govern the treatment as govern the treatment of such cases not associated with pregnancy.
4. Induction of labor should never be attempted in case of a decompensated heart until thorough trial has been made of medical measures. Disregard of this rule has often led to disaster.
5. Hard and fast rules to govern the decision to terminate pregnancy in heart disease cannot be set down. In general, if decompensation occurs early in pregnancy, if it does not respond to medical treatment, if it has been severe despite proper care in previous pregnancies and if the signs and symptoms indicate serious circulatory defect despite treatment, termination is usually wise.
6. The question of the method by which pregnancy should be ended is largely an obstetrical one, the point of greatest importance being the guarantee of a short and easy second stage. It should be remembered that if serious cardiac breakdown can be averted, it is wiser not to attempt delivery in advance of term. Cæsarean section is rarely necessary. Sterilization should come up for consideration in appropriate cases.

A Clinical Study of Quinidine in Auricular Fibrillation*

By DAVID FELBERBAUM, M.D.,
and
OSCAR BRENNER, M.D.,
New York.

Auricular fibrillation is the most frequent arrhythmia seen clinically. It makes up about forty per cent. to fifty per cent. of all irregularities. Until Wenchenbach in 1914 observed the remarkable effect of quinine in arresting the fibrillation of the auricles in two cases, and restoring the normal rhythm, digitalis was our only standby. But digitalis does not alter the abnormal mechanism. It merely blocks many of the rapid and irregular impulses bombarding the ventricles, thus causing them to beat at a slower and more efficient rate.

Experiments (1) upon animals have established that fibrillation of the auricles diminishes the output of the heart by forty per cent. and although clinically this deficiency may be remedied by the wonderful adaptability of the heart muscles and certainly materially so by the judicious use of digitalis, nevertheless the irregularity of itself, even under the best conditions, embarrasses the functional efficiency of the heart and the least provocation will cause failure of compensation, as the reserve force of these hearts are always curtailed.

It is therefore natural that a great deal of interest should be aroused by a remedy that will restore to a normal mechanism a fibrillating heart, and since Wenchenbach's original communication, many reports have appeared in the literature.

Frey (2) in 1918 systematically studied the various cinchona alkaloids in patients with this condition. He found that quinidine was most effective in this respect and least toxic. (Dextrorotary stereoisomer of quinine.) Quinidine sulphate is used because of its better solubility and quicker absorption. In his first communication Frey reported a series of ten cases in six of which he was able to revert the fibrillation back to the normal rhythm. Stimulated by Frey's remarkable results, many investigators studied the effect of quinidine sulphate, and up to the present date there has been recorded about five hundred cases, of which about fifty-one per cent. have been controlled by quinidine, at least temporarily.

PHARMACOLOGY.

The factors which determine the success or failure of the treatment are not as yet entirely understood. Pharmacological experiments on the action of quinine and quinidine on the heart have been done by Santesson (3), who, in 1893, showed that quinine and its alkaloids cause a retardation of the rate and a diminution of the force of the muscular contraction in the isolated frog's heart. Hoffman (4) in 1915 experimenting on dogs' and cats' hearts with perfusions of quinidine, demonstrated that the excitability of the auricular musculature was greatly diminished and that it required greater electrical shocks to produce contractions. Whereas, fibrillation could be easily induced by rhythmic induction shocks previous to the perfusion, it was impossible to do so after the perfusion. Boden and Newkirch (5) in 1920 studied the effects of perfusions of quinidine in isolated rabbits and human fetal hearts and obtained similar results.

In this connection the theory of the circus movement as the actual cause of fibrillatory mechanism is of great significance. In a series of recent articles Lewis (6) gives an ingenious explanation of the action of quinidine in restoring the normal rhythm by applying this theory. From experiments on animals he came to the conclusion that the refractory phase in the auricles is increased and thereby quinidine sets up barriers or local blocks in the ring in which the contraction wave is circulating. This blocking becomes so effectual in some cases that the normal sinoauricular node, which, in fibrillation of the auricles is submerged, can reassert itself and become the pacemaker of the heart. However, quinidine also increases the rate of conduction through the auricles. This tends towards continuing the circus movement, and it depends upon which of these two effects predominates, whether or not the circus movement will be abolished.

This theory is further strengthened by electrocardiographic studies of the action of quinidine in patients with fibrillation. The most noticeable feature is a conspicuous reduction of the rate at which the auricles beat, and in cases in which the treatment is successful, the progressive slowing of the auricular activity is abruptly brought to an end, the disordered action ceases, and the normal action is at once reestablished.

CLINICAL FACTORS INFLUENCING THE ACTION OF QUINIDINE.

Clinically, the type of valvular disease present has no effect as to the action of quinidine; neither does the age or sex influence it. Frey (2) and others comment on the fact that the duration of the fibrillatory state is the most important condition for success. The more recent the incident, the more likely the outcome will be successful. He says that cases in which the fibrillation followed recent trauma, operations or infectious diseases, as pneumonia, the results are prompt and lasting. Two thirds of the cases in which the fibrillation was present less than one year were restored to normal, while only four per cent. of those over one year, were affected by quinidine.

It is also essential to get the heart in as good a state of compensation as possible. The patient should be kept in bed, digitalized, and when compensation is fairly well restored, to discontinue digitalis for at least one week before beginning the course of quinidine.

ADMINISTRATION OF QUINIDINE.

The size of the doses of quinidine is of great importance. Jenny (8), who employed the largest doses, five tenths gm. at a dose, a total of two to three gms. a day, had the greatest percentage of success. In eighteen cases, seventeen or ninety-four per cent. were restored to the normal rhythm. On the other hand, Klevitz (9), who used very small doses, one tenth gm., had only one successful outcome in a series of thirteen cases, or only eight per cent. Most observers used the doses as originally employed by Frey namely, two tenths gm. This is given every two or three hours, as the drug is rapidly excreted.

---

*From the Medical Department, Montefiore Hospital, New York City.

In our series we first gave two preliminary doses—six hours apart—to guard against any untoward symptoms. If the patient stood the drug nicely, the next day two tenths gm. was continued every three hours for five doses daily. If, in three or four days, no effect was obtained, the dose was doubled and continued for a week or ten days longer, at the end of which time, if no results were obtained, the case was considered refractory. In a few of these another attempt was made a few weeks later, but we never succeeded when the case was refractory at first trial.

This report comprises a study of eighteen unselected cases and the results obtained are of interest in illustrating the alterations in the heart's action induced by the administration of quinidine, and the various toxic effects observed in these cases, as shown by subjective symptoms and the changes in the form of the electrocardiograms which may be ascribed to toxic effect on the heart muscle. The cases studied are divided into three groups: 1. Those cases in which the normal mechanism was reestablished. 2. Those in which the drug failed. 3. Those in which toxic effects were seen. A complete summary of all these findings is given in Table I.

CASES IN WHICH NORMAL MECHANISM WAS RESTORED.

In this group there were nine cases. The known duration of fibrillation in these cases vary from a few months to eight years. The amount of quinidine necessary to restore the normal mechanism varied from 0.4 gm. to 4.8 gms. The duration of the restored rhythm varied from three hours to eleven months. Five of these cases were in a state of decompensation when quinidine was first given, but no bad effects were observed. The type of valvular disease had no effect on the action of quinidine, neither did the age nor the sex influence the result. The duration of the fibrillation in all the cases restored was over one year. In one case eight years.

The change from the abnormal to the normal rhythm is sudden. Some patients were distinctly aware of the transition and asserted that they felt immediately better, the palpitation having been relieved. Others did not appreciate the difference. Frey notes that in sixty-six per cent. of his cases the effect lasted less than one month. In our series all but one case lasted less than two months. The longest duration of the restored rhythm so far reported are two cases by Boch (10), of one year's duration. The longest period maintained in our cases was eleven months. (Case I.)

In some of the patients that relapsed the effect was repeatedly reduplicated. In one, nine relapses were restored with from eight tenths to one gm. of quinidine. (Case VII.) Another has been restored twice.

Cases	Age	Sex	Etiology	Valvular Lesions: Mitral	Valvular Lesions: Aortic	Valvular Lesions: Combined	Card. Enlargement	Known Duration of Fibrillation	Rhythm Restored	Amount Necessary for Restoration	Total Amount Administered	Duration of Admin. Days	Duration of Rest Rhythm	Symptoms Complained: Precordial Pains	Palpitation	Headache	Dyspnea	Tachycardia	Vertigo	Nausea and Vomiting	Abdominal Pain	Deep cyanosis	Flushing	Remarks
1.	45	F	Rheum.			+	+	2 yr.	+	2.3	7.1	9	11 mo.										+	Six mos. before admission emboli in medulla, causing cruciate hemiplegia ventricular extrasystole.
2.	49	M	Rheum.			+	+	1 yr.	+	4.8	19.3	25	48 hr.	+				+			+			Flutter for eleven days Heart enlarged further decompensation increased.
3.	55	F	Rheum.	+				2 dy.	+	2.0	7.1	5	24 hr.			+				+			+	Left hospital. "T" variations.
4.	39	F	Rheum.	+			+	1 yr.	+	2.5	4.8	4	4 dy.				+			+				Restored twice, 7.8 gm. no effect on fibrillation on second relapse. Third attempt restored for three days after 6.7 gm.
5.	50	F	Art.Scl.	+				1 yr.	+		2.2	3	3 hr.	+	+		+	+						Vent. tachycardia resulted after two trials. "P. R." interval increased.
6.	38	M	Rheum.	+			+	8 yr.	+	1.5	8.	6	12 hr.	+	+	+	+	+	+					Nine relapses restored with .4 to 4.0 gm. "T" variations.
7.	37	F	Rheum.	+			+	4 yr.	+	.4	.4	1	2 mo.											
8.	54	F	Art.Scl.	+			+	6 mo.	—		11.2	13			+								+	Ventricular tachycardia.
9.	50	M	Rheum.	+			+	1 yr.	—		13.8	15			+	+	+							
10.	55	F	Art.Scl.	+		+	+	8 mo.	+	3.	4.1	9	24 hr.											
11.	55	F	Rheum.	+			+	1 yr.	—		5.7	6												
12.	14	F	Rheum.	+			+	6 mo.	—		6.0			+		+	+							
13.	30	F	Rheum.	+			+	1 yr.	+	1.2	6.8	19	12 hr.	+		+	+							Normal mechanism restored for twelve hours on second attempt.
14.	19	F	Rheum.	+			+	7 yr.	—		4.8	5		+		+		+			+			Two attempts 4.2 gm. given, no effect.
15.	18	F	Rheum.	+			+	2 yr.	—		4.8	5		+				+						Rhythm restored once at another hospital with quinidine lasting 24 hours. Present attempt increased edema, etc.
16.	36	F	Rheum.	+			+	3 yr.	—		0.2	1			+		+	+				+		Following first dose of .2 gms. marked cyanosis and dyspnea, refused further treatment.
17.	38	M	Rheum.				+	2 yr.	—		9.0	7			+		+			+				Compensation broke down, liver enlarged, râles in chest. Two weeks' rest and digitalis restored compensation.
18.	38	F	Rheum.		+		+	2 mo.	—		0.4	1			+	+			+					Refused further treatment after second dose because of distress.

(Case IV.) But sooner or later these become refractory to the drug, so that in only a small percentage is a prolonged effect possible. The reason for this is that the underlying cause which originally precipitates the fibrillation is not removed by quinidine, it merely arrests the disordered mechanism, the tendency toward fibrillation remains in nearly all the cases.

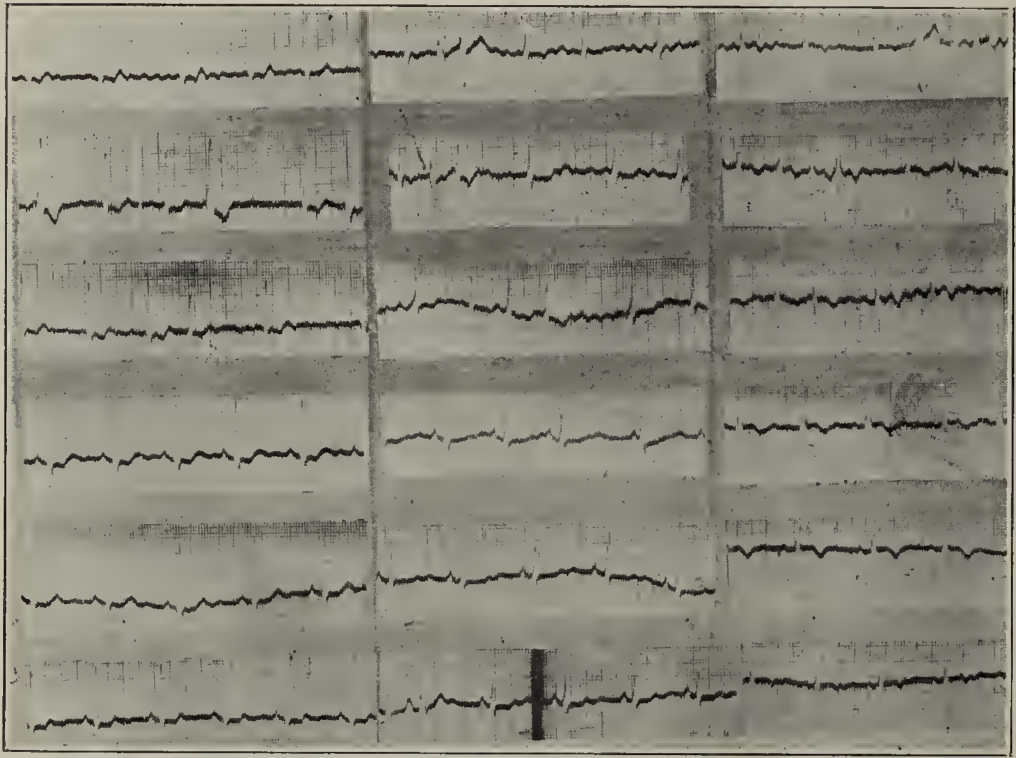

FIG. 1.—Shows restoration of normal mechanism occasional extrasystole and variations in the "T" wave.

The effect on compensation varies. Some cases are much improved, the clinical signs of decompensation disappear. In others practically no beneficial effect is seen. This depends entirely on the condition of the myocardium. If it be badly diseased and the cardiac reserve is low, correcting the abnormal rhythm cannot improve the efficiency of the heart. Furthermore, compensation may be greatly diminished by the tachycardia induced by quinidine, either the simple tachycardia alone or the more serious auricular flutter and ventricular tachycardia occasionally seen following quinidine administration.

It would seem reasonable to assume that with the restoration of the normal mechanism cardiac enlargement would show material change. That is, become smaller; because the circulation is carried out in a more efficient manner. We have made studies by means of teleoröntgenograms of nine cases in which quinidine was employed.

In five of these the rhythm was restored and teleoröntgenograms were made before and after the change in the mechanism of the heart beat. In one case (Case III) there was a definite diminution of the heart, but in this case the fibrillation had come on a few hours previously and was promptly restored by quinidine. In Case II there was a definite enlargement in the size of the heart found in the teleoröntgenogram taken during the relapse from the effect of quinidine. It was not possible, in this case, to restore the rhythm a second time; on the contrary, quinidine produced a state of constant flutter during the eleven days of its use. The heart failure became progressively worse and the enlargement was made out during this time. In all the other cases no change in the size of the heart was evident. It is therefore apparent that the mere restoration of the rhythm does not affect the size of the heart, in the ordinary type of auricular fibrillation. On the other hand, it may decidedly enlarge the cardiac diameters due to the extreme rapidity and ineffectual cardiac contractions, causing exhaustion of the myocardium with its accompanying dilatation.

CASES IN WHICH QUINIDINE WAS UNSUCCESSFUL.

In nine cases it was found impossible to restore the rhythm, the total amount of drug used varied from 4 to 13.8 gms., and was continued from five to eighteen days. In some cases the single doses were doubled. It is seen from analyses of these cases that the patients complain more of the subjective untoward symptoms than the previous group. They frequently require prolonged treatment with digitalis and rest in bed following the administration of quinidine, before the circulation is restored to its previous condition.

UNTOWARD EFFECTS.

In our series no fatalities occurred. However, alarming symptoms may arise, such as deep cyanosis, severe dyspnea and cessation of respiration. In only one patient was cyanosis produced and this occurred with the second trial dose. It promptly disappeared with the discontinuance of the drug. (Case XVI.) Usually the patients complain of palpitation, slight dyspnea and tachycardia. Headache, vertigo, occasional abdominal pains and vomiting was seen in our series. Curiously, none of our patients showed any

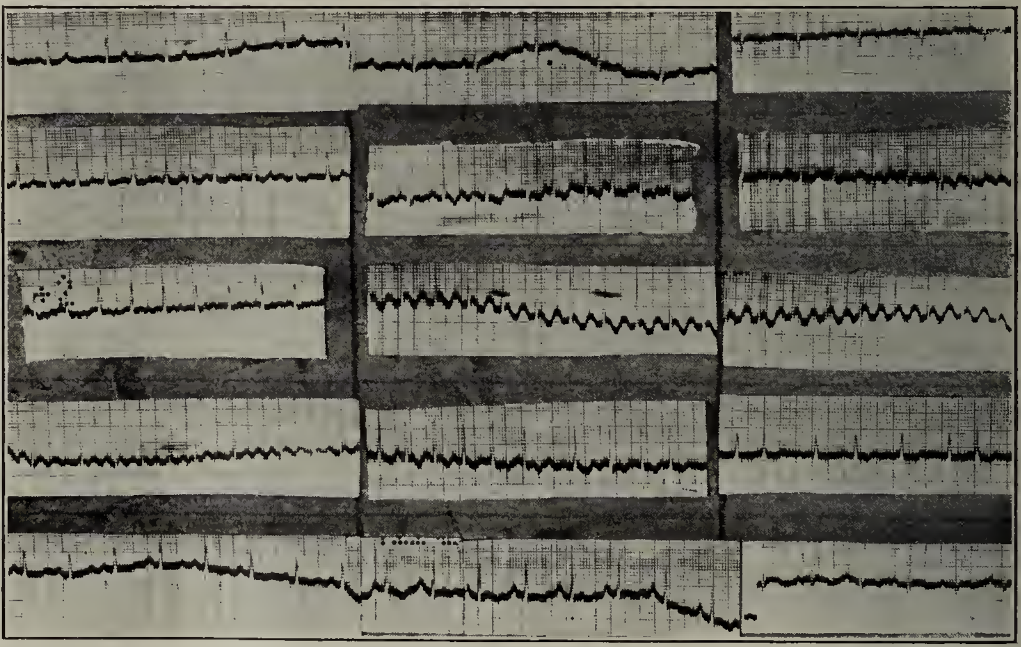

FIG. 2.—Shows restoration of normal mechanism on two occasions, demonstrating the slowing of the auricular complexes and transitory auricular flutter.

symptoms of cinchonism. Fatalities have been recorded by Benjamin and Kapf (11) (two cases), Bergmann (12) (one case), Hewlett and Sweeney (13) (two cases), Hay (14), (one case). But in only three of these could the fatality be ascribed directly to the drug, as most of the patients were in poor condition before the drug was employed. Death in these cases usually occurred suddenly within twenty-four hours after the normal rhythm was reestablished. Another possible danger is the breaking up of an auricular thrombus and disseminating emboli throughout the circulation. Frey, Ellis and Clark-Kennedy (15) and Levy (16) report such occurrences. In this connection it is interesting to note the histories of two patients which we observed, in whom previous to the use of quinidine and while the auricles were in a state of fibrillation, cerebral emboli had occurred. Both of these reacted promptly to quinidine without any embolic phenomena.

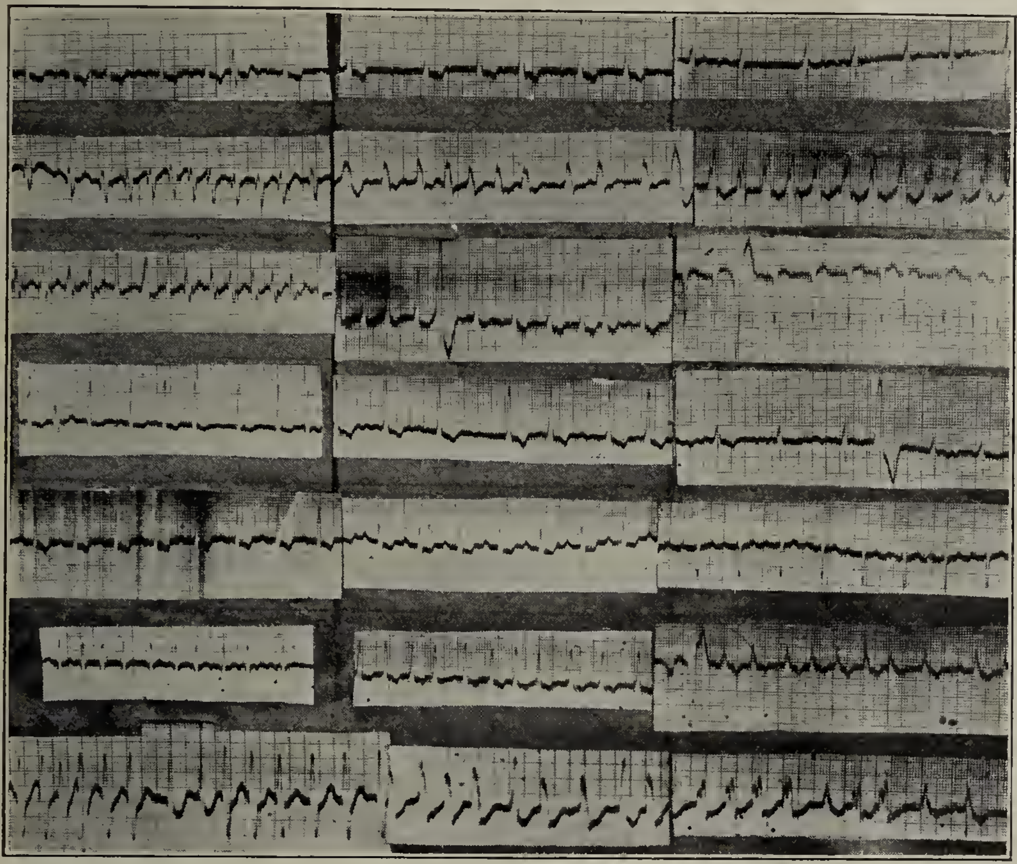

Fig. 3.—Demonstrates prolonged paroxysm of ventricular tachycardia, showing the abnormal complexes which were produced on two separate administrations of quinidine. June 17, 1921, mechanism became normal with a prolonged "PR" interval.

Case I.—Female, aged forty-five, admitted August 2, 1921, diagnosis, chronic cardiac valvular disease involving both mitral and aortic valves. The known duration of fibrillation was two years. Three months before admission she had an embolus in the bulb cerebri, causing a cruciate hemiplegia. (Right face and arm and left leg.) The first dose of quinidine was given on October 26, 1921. On October 28th, after 2.3 gms. had been taken, the mechanism of the heart beat became normal. There were no untoward symptoms and the mechanism had been normal ever since. That is, eleven months. The patient is comfortable and able to get about. (Fig. 1.)

Case II.—Female, aged thirty-nine, diagnosis, rheumatic cardiac valvular disease, mitral stenosis and regurgitation. The known duration of fibrillation was one year, the cardiac disease dated back twelve years. Admitted August 13, 1921.

Seven months before admission there suddenly developed a right hemiplegia with a motor aphasia. This patient was given quinidine sulphate on four different occasions, the normal rhythm being restored twice. There were no untoward symptoms on either occasion. The patient died November 7, 1922. Autopsy revealed a large mural thrombus in left auricle and recent multiple emboli in lungs and kidneys.

ELECTROCARDIOGRAPHIC CHANGES.

Various changes in the electrocardiograms have been reported, the most common observation being a slowing of the auricular deflections, while the ventricular rate increases. This slowing of the auricular complexes gradually becomes more marked and passes into a state of flutter. When frequent electrocardiographic records are made these changes are invariably seen in cases in which the mechanism is restored. (Fig. 2.)

Other changes were occasional increase in the auricular ventricular conduction time. This was noted once in our series (Case V) (Fig. 3). Various changes in the form of the T wave were seen, such as inversion, bifid character and constant variation in the height. Three cases showed such changes. The meaning of these changes is not known; possibly they are minor toxic effects of the quinidine upon the ventricles.

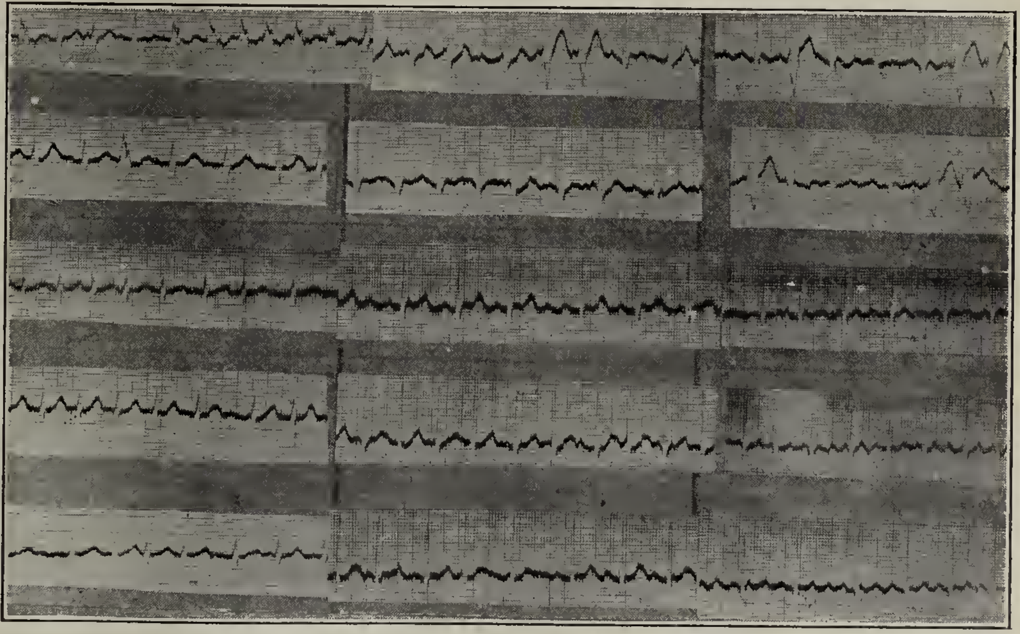

Fig. 4.—Shows the production of runs of ventricular extrasystoles gradually disappearing with the discontinuance of quinidine.

A more common disturbance seen are extrasystoles both auricular and ventricular, occasional runs of extrasystoles were seen (Fig. 4), but the most interesting change of all is the production of a paroxysmal ventricular tachycardia. This was seen in two cases, in one of which it was reproduced during a second trial (Fig. 3). It is possible that some of the fatalities reported in the literature were caused by such paroxysm passing into a state of ventricular fibrillation. It is absolutely essential that quinidine should be discontinued as soon as frequent ventricular extrasystoles are recorded in the electrocardiograms, especially if these tend to run in series.

SUMMARY.

1. Quinidine arrests auricular fibrillation and restores the normal rhythm in about fifty per cent. of unselected cases. The effect is temporary in the majority and only in a small percentage will the result be lasting.

2. There are certain dangers to bear in mind in the administration of quinidine, namely, the possibility of disseminating emboli through the circulation, and certain toxic effects on the ventricles which may possibly lead to a fatal termination.

3. The use of the drug is still in an experimental stage and should only be used in institutions where careful electrocardiographic examinations are possible.

The Control of Paroxysmal Tachycardia by Quinidine Sulphate*

By C. C. WOLFERTH, M.D.,
Philadelphia.

It has been shown by the work of Santesson (1), Hofmann (2), Boden and Neukirch (3), Schott (4) and others that the effects of quinidine on the normal heart are in the main depression of the various functions of cardiac muscle. It is generally agreed that conductivity in the specialized conduction paths, excitability and contractility are sharply depressed. The evidence as to the effect on stimulus production is not so clear. Some workers have found that quinidine slows the rate of the heart, but others have failed to obtain this effect.

Lewis and his coworkers (5) have recently stated that the refractory period of heart muscle is increased by quinidine and conduction of the excitation wave through nonspecialized muscle is slowed. To the increase in refractory period they attribute the well known effect of quinidine in terminating auricular fibrillation and flutter. The retardation of the excitation wave, on the other hand, tends to help preserve the abnormal rhythm. The result of treatment in any given case, they believe, depends on which of these effects is predominant.

The cause of paroxysmal tachycardia is not definitely known but it is believed that increased excitability in some ectopic focus is a factor in its production. Since quinidine has been shown experimentally to have a marked effect in depressing excitability, it is reasonable to expect that the drug might exert a favorable influence in preventing or terminating attacks of paroxysmal tachycardia.

Boden and Neukirch (3) have reported briefly their experiences in giving quinidine by intravenous injection during attacks of paroxysmal tachycardia. In six cases studied, the attacks were abruptly terminated in four and the rate slowed in two. Romberg (6) has also been successful in terminating attacks with quinidine. Haass (7) treated two cases without result. Whether he tried to terminate attacks or prevent their occurrence is not stated. Romberg has expressed the view that quinidine might be found of value in preventing the onset of attacks in cases in which they are numerous. Thus far there have been no reports bearing on this point. This is probably due to the comparative rarity of cases in which attacks occur so frequently and constantly that conclusions can be drawn confidently as to the effect of treatment. Recently, a woman with paroxysmal auricular tachycardia came under observation in the medical division of the University Hospital. Her attacks occurred day after day with such frequency that the case was regarded as an exceptionally favorable one in which to note the effect of quinidine.

REPORT OF CASE.

CASE I.—G. G. G., a white woman, forty-seven years old, applied for treatment at the medical dispensary of the University Hospital, complaining of attacks of palpitation. Ever since an attack of influenza in April, 1919, she had suffered from paroxysmal attacks of rapid and forcible heart action accompanied by shortness of breath, a smothering sensation, faintness, dimness of vision, and precordial pain. At first the attacks came only occasionally, but during the past three months they had been much more frequent. They occurred most often when she exerted herself, also when she was sitting quietly, but never when she was lying down. She had suffered a great deal from backache since the birth of a child twenty-eight years ago. For six months she had had a dull throbbing pain in her hips, worse on walking and on lying on either side. She could not sleep unless she lay on her back, consequently her sleep was disturbed. At the time the hips began to cause trouble, the ring finger of her right hand became swollen and painful. Her appetite was good but sometimes she had a sour stomach and regurgitation, which, however, responded readily to sodium bicarbonate. Her weight was 240 pounds, which was the most she had ever weighed.

She had ,had pleurisy at the age of fifteen and typhoid fever at twenty-four, and repeated attacks of tonsillitis. In 1902 a bilateral oophorectomy was done which brought on an artificial menopause. The year after this operation her weight increased from 130 to 200 pounds and since that time she had gradually gained forty pounds. In 1908 two operations were performed for adhesions and bladder trouble. In 1911 she was operated on for incisional hernia. She was a housewife and had always worked hard. She ate unusually large amounts but otherwise her habits were good. Her first husband was killed in an accident. Her second husband and a daughter, her only child, were living and well. There had been no miscarriages. The family history was unimportant.

---

*From the Medical Division, University Hospital, and the William Pepper Clinical Laboratory, University of Pennsylvania.

Physical examination showed a woman, short, very fat, who looked about her stated age, forty-seven years. Between attacks she was placid but during the attacks she was somewhat apprehensive, although there were no external evidences of great discomfort. She was able to note accurately the beginning and ending of attacks, apparently never making a mistake in this respect. There was no cyanosis nor evident shortness of breath as she sat quietly. A few fine, moist râles were heard at the bases of both lungs which quickly disappeared after a few deep breaths. The cardiac apex impulse was situated in the fifth interspace with its outer border twelve cm. to the left of the midsternal line. By percussion, the cardiac area extended three cm. to the right and twelve cm. to the left of the midline. There was reduplication of the first sound at the apex but no murmur nor accentuation of sounds. For periods of several minutes the rate might be 60 to 70 a minute and regular, except for occasional premature contractions. Suddenly there was an onset of regular or slightly irregular rapid rate varying from 165 to 180 a minute in different attacks. The pulse which previously had been of good quality became small and soft and there were marked pulsations in the vessels of the neck. The attacks lasted from thirty seconds to several minutes and stopped as abruptly as they began. The abdomen was fat and pendulous and there was a long operation scar extending from the ensiform to the symphysis pubis. There was a small incisional hernia in the lower part of the scar. The liver was not palpable, nor demonstrably enlarged. There was swelling, redness, and tenderness of the first interphalangeal joint of the right hand, moderate varicosities of the veins of the legs, slight pitting on pressure about the ankles, and extreme flat feet. The reflexes were normal and the blood pressure 160/105.

The laboratory examinations showed that the urine contained traces of albumin and a few hyaline and light granular casts; otherwise negative. The blood count was entirely normal. The Wassermann was reported medium positive. The phthalein excretion was fifty per cent. in two hours, and the blood urea nitrogen was ten mgm. to one hundred c. c. Teleröntgenogram of the heart showed it to be definitely enlarged with a transverse measurement of 19.5 cm. X ray studies of the swollen finger and the sinuses were negative. The electrocardiograms showed the rapid heart action to be due to paroxysmal auricular tachycardia (Fig. 1). The irregularity in some of the attacks was caused by associated partial block with occasional dropping of ventricular beats (Fig. 2).

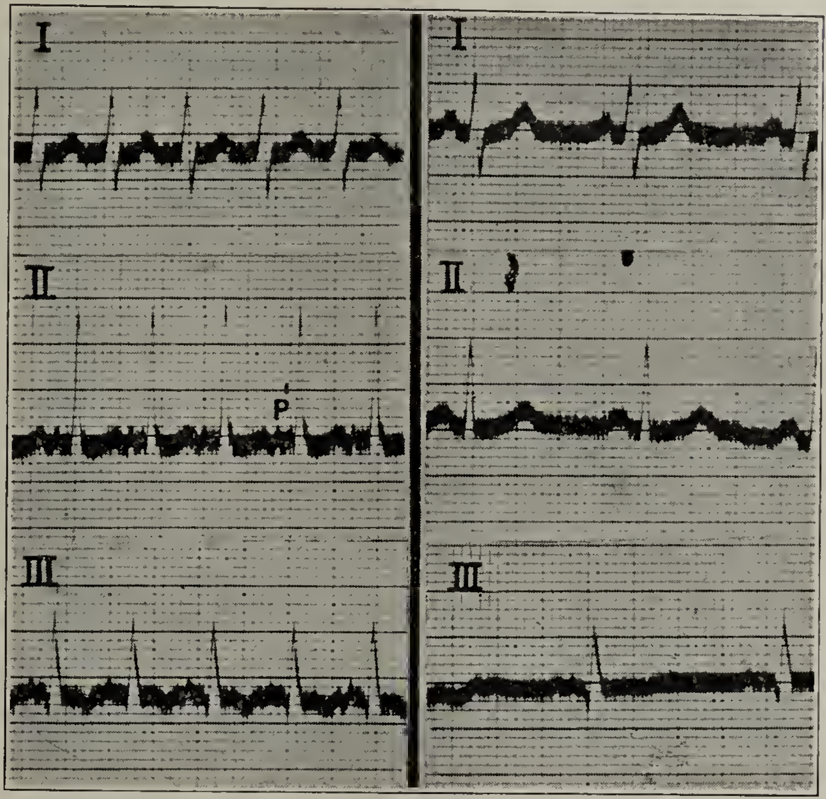

Fig. 1.—The tracing on the right shows a paroxysm of auricular tachycardia with a rate of 171. The ventricular action is regular. The tracing on the left was taken immediately afterward. The rate varies between 71 and 83.

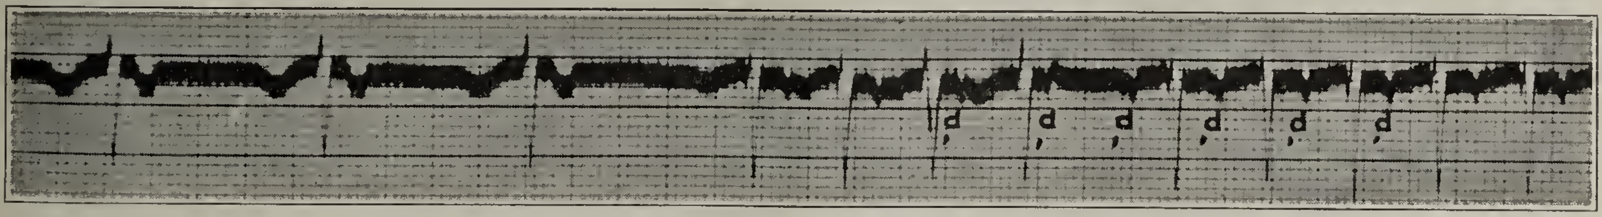

Fig. 2.—The end of a paroxysm of tachycardia. Regular auricular tachycardia but irregular ventricular action due to partial auriculo-ventricular block. No evidence of disturbed conduction after the mechanism returned to normal.

Between November 9th and 25th, the patient visited the medical dispensary three times. No drug treatment was given except some salicylates for the pain in the joints. She was advised to stop working and remain as quiet as possible. The attacks increased in frequency so that by her third visit the intervals between them were very short except when she was in a recumbent position. She was then referred to the ward for treatment. She was admitted to the ward on November 25th and immediately placed on a régime of restricted diet and rest in bed most of the day. At first she was allowed up about three hours a day. The question of the possible cause of the joint pains and the attacks of paroxysmal tachycardia was again considered. On account of the frequent attacks of tonsillitis, the tonsils came under suspicion, although they were very small and innocent looking. Because of the report of a medium positive Wassermann, it was thought that there might be a syphilitic myocarditis. On November 26th she was given two doses of quinidine sulphate, 0.2 gram. The next day the amount was increased to 0.4 gram three times a day and the number of attacks decreased. On November 29th the dose was further increased to 0.6 gram three times a day and only one attack occurred all day. The next three days 1.0 gram three times a day was given and there were no attacks. On December 3rd the dose was reduced to 0.4 gram three times a day and there were several attacks. From then on, during the remainder of her stay in the hospital, a period of two weeks, 0.8 gram three times a day was given. During the first four days of this dosage, there were two slight attacks, but in the next ten days, no attacks at all were noted by the patient and none discovered upon examination. During this time, her activity was gradually increased until she was up and about the ward all day. On December 5th mercurial inunctions were instituted but they were so badly borne that only four were given.

She was discharged from the hospital on December 18th. In view of her tolerance of quinidine and the improvement in physical strength and the abolition of the train of cardiac symptoms while in the ward, it was considered justifiable to permit her to continue taking the same amount of the drug after leaving. There were no further attacks until December 27th when she noticed three. On that day she had failed to take her medicine. She was then advised to take 0.4 gram four times a day, which she did for several days but had a few attacks during this time. The dose was then increased to 0.4 gram five times a day. On January 13th, the dose was again cut to 0.4 gram four times a day, which up to February 13th was enough to prevent the paroxysms. Whenever the dose was cut below this amount, attacks recurred. There had been a steady improvement in her tolerance to exertion so that she was able to do her work without difficulty.

Electrocardiograms taken on a number of occasions showed no depression of auriculoventricular conduction and no changes in the ventricular complexes except slightly less amplitude of the T wave in Leads I and II.

In attempting to judge the effect of quinidine in controlling the attacks of paroxysmal tachycardia in this case, the factors of rest and altered diet must be taken into consideration. It might be argued that the control of attacks following the patient's admission to the hospital could be ascribed, at least in part, to the restricted diet and the low plane of physical activity. This would not, however, explain the recurrence of attacks when the dose of quinidine was reduced nor their control when it was again increased, an experience which was repeated many times. The facts seem to demonstrate that quinidine was the important factor in controlling the attacks.

The amounts of the drug tolerated by this patient over long periods of time are unusual but this may be accounted for in part by her great weight. Nevertheless, judging from our own experiences and from the published reports, corresponding doses, calculated according to body weight, might be expected to bring on, in many patients, definite symptoms of depressed cardiac action. But in view of the marked clinical improvement in this patient, it seems reasonable to assume that whatever depression of contractility may have been caused by the drug was more than compensated for by the increased cardiac efficiency produced by undisturbed normal cardiac mechanism.

The effect of the drug in preventing attacks was found to be transient, distinctly less than twenty-four hours. Consequently, administration in divided doses every day seems to be the proper method in this type of case. It was hoped that suppression of the attacks might result in recovery of the heart muscle to such an extent that their spontaneous occurrence might be greatly reduced or abolished. Thus far, there seems to be no evidence that this has been accomplished.

Obviously, this form of treatment is not to be recommended unreservedly in the treatment of paroxysmal tachycardia. The administration of quinidine is apparently not without danger even in patients with comparatively healthy hearts. But the results observed in the case reported would seem to warrant further study of patients in whom the ordinary methods of managing paroxysmal tachycardia are ineffective and the attacks are so numerous that the capacity of the heart to carry on its work is seriously threatened.

A case of paroxysmal tachycardia is reported in which the attacks were extremely numerous and of short duration.

A definite influence on the frequency of attacks was exerted by quinidine sulphate; by administering sufficient amounts of the drug, the attacks could be completely suppressed.

Myocardial Degenerations and Their Treatment

By ALBERT E. ROUSSEL, M.D., O.A., F.A.C.P.,
Philadelphia,

Professor of Medicine, Graduate School of Medicine, University of Pennsylvania; Visiting Physician to the Polyclinic Hospital, etc.

In a previous communication, published in 1905, I pointed out that, contrary to general opinion, diseases of the myocardium were more frequent than those of the endocardium, and quoted the statistics of Schott that the proportion was 505 to 245. More recent observations, based largely on postmortem examinations, prove conclusively the truth of these observations, which is not sufficiently appreciated by the profession. This does not include the myocardial changes secondary to valvular lesions, which again are, in the majority of these instances, the actual cause of death.

It is fortunate that a better appreciation of these facts, together with the additional aids to diagnosis afforded by the fluoroscope, orthodiagram by x ray methods, the electrocardiogram, the sphygmomanometer, the polygraph, when a plebogram, a cardiogram and a sphygmogram are to be taken at the same time, results in the more general as well as earlier recognition of these important conditions.

Most infections, including the focal type, various toxemias, acute and chronic, some dyscrasias, anemia, various intoxications, thromboses, and emboli, if of a certain degree of intensity, produce changes in the heart muscle which may be acute or chronic, temporary or permanent.

Albuminous degeneration—one of the early changes—is a condition met with in infectious diseases, diphtheria, smallpox, typhoid, typhus, remittent fever, tuberculosis, lobar pneumonia, erysipelas, influenza, measles, septic processes, gonorrhea, and even a comparatively slight attack of tonsillitis. It is probable that in addition to the toxins generated, in many of these instances where continued fever is present this may also be a factor. This form of degeneration is characterized by a pale, turbid condition involving in most instances the entire cardiac muscle and relaxed, soft, brittle walls. In the acute form suppuration may result, or it may resolve into the chronic form.

Arteriosclerosis must be accepted as an important factor in many, but not in all cases, of cardiac degeneration. It is worthy of remembrance that at least partial occlusion of the coronary arteries due to this cause may be compensated through the vessels of Thebesius with avoidance of otherwise resulting damage. Much more often, however, as a result of the diminished blood supply, the parts undergo an anemic necrosis with resulting change in the muscular fibres either in loss of their nuclei or, as shown by J. Renaut (1889), fragmentation or fracture of the fibre itself. Some of these cases may be postmortem phenomena. If the development is a more gradual one the muscle fibres which have undergone this anemic necrosis are replaced by fibrous tissue with resulting increase in the size of the heart and subsequent gradual or sudden dilatation of its walls.

An important point to be remembered is that one of the most common causes of sudden death is due either to sudden obliteration by a thrombus of one coronary artery which has been narrowed by arteriosclerosis or endarteritis.

Myocardial degeneration secondary to hypertrophy and dilatation, the result of overstrain in athletics, is far more common than is admitted, and when the heart is called upon for reserve force in an acute illness it is often found wanting. I cannot refrain from quoting from an address I delivered before the Philadelphia College of Pharmacy in 1895:

"You cannot have failed to note the short duration of life of many athletes. Any acute disease, such as pneumonia, typhoid fever, and others, that during its course calls upon the heart for extra reserve force, even when no apparent cardiac disease exists, is particularly to be dreaded in this class of cases, and for my own part I would much prefer treating a case of pneumonia in an apparently scrawny, illdeveloped clerk who has never even handled a dumbbell, than in one of our overdeveloped athletic subjects." Recent observations on the socalled soldier's heart tend to confirm these statements.

The various tachycardias may sometimes result in cardiac changes, but not nearly so often or so pronounced as most authorities believe. I have at present under my care a neurotic young woman whose pulse rate has been between 100 and 130 for the past three years, with but very slight cardiac hypertrophy. Some years ago I began to believe that some of these cases were due to hyperthyroidism without the evidence of goitre or exophthalmos, and acting on this belief I had had three patients operated upon for the relief of the tachycardia by ligation. More recent experience with basal metabolism has confirmed this, but I now have them treated by intensive dose of x rays.

In the first case the result was a perfect cure after one year's duration; in the second there was marked amelioration, while in the third—the one alluded to above—the condition remained as before operation.

Necessarily, syphilis, rheumatism, gout, and occasionally diabetes, are the important etiological factors in this degenerative change. The first two diseases should give a positive history, but an important fact, which is not appreciated as much as it should be, is that true gouty subjects (rare in this country) are less likely to show myocardial change than those in whom the joints have never been inflamed, but who suffer from other irregular manifestations of the disease. This American gout, or lithemia, which is often difficult of recognition, is doubtless in many instances an explanation of those cases in which an apparent etiological factor could not be found. Recent observations would seem to prove that spinal fluid findings would be of value in cardiovascular diseases when syphilis is suspected and the blood Wassermann test is negative.

In rheumatism the nodules of Aschoff—a small collection of cells in the myocardium—are probably inflammatory, and it is interesting to note that they are more apt to be found in those cases which have presented evidences of subcutaneous rheumatic nodules.

The term fatty heart means fatty overgrowth with resulting fatty infiltration between the muscle fibres, and not infrequently resulting fatty degeneration. The first is an abnormal development of fat in or between the muscular substance of the heart, often impairing the contractile power, and not infrequently resulting in actual fatty degeneration. Hereditary predisposition exercises a marked influence on the occurrence of obesity, and no doubt also on resulting fatty infiltration. The condition is more than twice as common in the male as in the female, and is generally found after middle life. Improper food, sedentary habits, alcoholism, particularly in the consumption of malt liquors, are important factors.

Most of the cases of fatty heart are found in corpulent subjects and the simple reduction of weight in these cases is unfortunately not often accompanied by a corresponding improvement in the cardiac condition.

Fatty degeneration is a change in the muscular fibres, by which the transverse striæ disappear, being replaced by granules and globules of fat—a condition of defective nutrition, and therefore the result of various causes, old age perhaps, associated with fatty infiltration, anemia, either primary or secondary to repeated hemorrhages, or wasting diseases, phthisis, cancer, and chronic suppurating, prolonged fevers, chronic alterations of the blood, purpura, scurvy, hemorrhagic diathesis, certain poisons, phosphorus, arsenious acid, lead, antimony, and, last but not least, alcohol. Local causes, such as pericarditis and hypertrophied ventricular walls, as well as disease of the coronary arteries, may bring it about. The distribution of this change varies. When secondary to acute diseases it is generally uniform, but in the majority of all cases the left ventricle is more affected than the right.

A point of importance, as shown when we entertain the question of diagnosis of both of these conditions, is that the size of the heart may be normal or only slightly increased by the occurrence of secondary dilatation and occasionally it is diminished. This condition, however, may and often does occur in hearts previously enlarged.

Brown atrophy is a not common degenerative change, but may exist in that portion of the heart muscle near affected valves. In the old and those who have died from wasting diseases it may be present. I have seen several marked postmortem evidences of this kind in patients who have suffered repeated and profuse hemorrhages from uterine fibroids. In several other instances of a similar nature I have been so impressed by the physical signs and symptoms of a weak heart that I have enjoined particular caution in the administration of ether in those cases where operations were indicated.

Amyloid degeneration is rare and not often recognized macroscopically. Waxy and hyaline degeneration is often found in acute infections and toxic conditions. Myocarditis of rheumatism is a fibrositis or typical infiltration of tissue outside of muscle bundles.

The consequences of myocardial disease necessarily depend upon the degree and character of the affection, and to a certain extent upon the parts involved. In all cases, however, the result must be loss of contractile power and thus lead to imperfect filling of the arterial system and consequent visceral anemia. This, it is to be noted, is much more marked than is the correlative venous distention, which is so prominent an effect of dilatation of the heart.

In the fibroid heart, hypertrophy and dilatation usually coexist, and suggest at least recognition of the heart as the main issue involved. Dyspnea and dropsy are sooner or later present and the symptoms resemble those of dilatation of the heart. The first sound is weak and toneless and has been noticed to be weaker over the left than over the right ventricle when the former was more affected. A mitral systolic murmur may be present, but perhaps recognized only in the recumbent posture. The pulse is weak, irregular on exertion, normal frequency, or may be as infrequent as 30. The tension is as a rule high. Cardiac pain may be present, but rarely to a marked extent. In many instances, however, the symptoms have been remarkably latent and death may be sudden apart from rupture or even the existence of an aneurysm.

The recognition of a faint cardiac murmur is sometimes one of considerable difficulty. Ashner noted that in the most normal individuals pressure on the eyeball causes a slowing of the pulse rate up to ten beats to the minute through vagus inhibition, and Loeper and Moregeot, in December, 1913, noted the abolition of this reflex in tabes.

This cardiac inhibitory reflex may be considered as the bilateral group of cells in the medulla at the level of the nuclei of origin of the vagi, and when the tonic action constantly exerted through this centre is increased, cardiac inhibition results.

I have been much interested in this subject and for the past several years I have applied this method in the examination of all of my heart patients, and find that even in those cases where no apparent reduction in frequency is effected, and in a few cases where it is increased, in the majority of instances this pressure exercised for about two minutes will not only accentuate existing organic murmurs, sometimes to a marked degree, but will also bring out a previously unsuspected murmur. On the other hand, functional murmurs would seem to diminish in intensity or entirely disappear. The test is easily made and merits recognition.

Mackenzie speaks of physiological murmurs, particularly in younger subjects, occurring in apparently normal persons.

The diagnosis of many cases of fatty degeneration is to my mind even more difficult than that of a fibroid heart, and I am positive that often cases of this disease are not recognized even after a physical examination. This is due largely to the fact that as the size of the heart in simple, fatty degeneration may be little changed, the area of dullness may present no alteration on account of this slight dilatation that exists. It must be remembered, however, that in other cases fatty degeneration follows preexisting hypertrophy and dilatation. Significant are evidences of diminished force of impulse, the area which may remain normal. Of course, if dilatation has occurred the impulse is diffuse. Both sounds are weakened corresponding to the impulse, but necessarily the first sound shows the greater alteration on account of the muscular element; it is of less volume, shorter in duration, and higher in pitch, resembling the normal second sound, which is of course correspondingly diminished on account of the weakened distention. In some cases it is alone discernible.

The first silence is longer than normal on account of the shorter first sound. Thus the sounds resemble those of the fetal heart, particularly when the action is rapid. If on repeated examinations where the area is not increased there is noticed a greater relative diminution of the aortic second sound than of the pulmonic, it is fair to assume that the left ventricle is chiefly affected and vice versa. The greater involvement of the left ventricle can thus be demonstrated in the parenchymatous change resulting from high temperature in typhoid and other fevers.

The rhythm varies greatly. Extrasystoles, auricular fibrillation, auricular flutter, irregularities and abnormal rhythm due to injury of the conducting system, pulsus alternans may all be the expression of an injured or impaired heart muscle. The action of the heart may be regular and normal in frequency, particularly if dilatation is not marked. The source of the action of the heart is now placed in the muscle itself, and Gaskell describes as its functions rhythmicity, excitability, contractibility, conductivity, and tonicity. Consequently any of the various forms of arrhythmia may occur, including complete heart block and Stokes-Adams disease, also fibrillation. It must be remembered, however, that occasionally some of these conditions may occur and continue for years without recognizable existence of cardiac disease, and are quite often found in children. However, infrequency of pulse with or without hypotension, when observed after middle life, is, to say the least, suggestive.

An active business man applied for an increase of twenty thousand dollars of insurance, which was granted. Some weeks afterward he called my attention to the fact of the lowering of his pulse rate to about fifty-eight. A careful examination revealed evidences of cardiac degeneration, and notwithstanding treatment he died in an attack of angina (the first) within three months of his insurance examination.

I have always taught my classes to differentiate in the use of the terms frequent and quick as applied to the pulse. Frequency has to do with the number of beats to the minute, while quickness applies to the duration of the pulse wave. Conversely the difference between infrequent and slow should be noted.

Cardiac oppression and pain are frequently present, but are not always indicative of the severity of the case. I must agree with those who object strongly to the term false angina pectoris as differentiated from the true. Pains produced elsewhere and referred to the heart should be called extracardiac. But, on the other hand, it is important to recognize the frequency of epigastric pains and occasional epigastric Head's zones found in heart disease and probably the result of referred nerve excitation. These may explain the still too frequent and unwarrantable reports of sudden death from acute indigestion. I believe also that attacks of angina pectoris must be accepted to vary greatly in the degree of severity and need not present the classical description of the extreme degree, which to my mind frequently shows an advanced condition and consequent early death. Therefore the lesser degree, or anginoid pain, especially on exertion, is apparently no more dangerous than other cardiac symptoms. Indeed it must be remembered that cardiac pain produced by overexertion may occur in a perfectly healthy heart. On the other hand, its occurrence and continuance while at rest has an entirely different significance. Toxic angina in women is often less serious and may be due to intestinal tract with hyperesthesia of skin and muscles of abdomen often on one side. Aortitis, often due to syphilis, may produce a paroxysmal pain high in the chest and sometimes to the back of the neck without radiation. Tenderness on pressure of the left breast, so marked, may produce an attack of angina.

Early dyspnea, frequently with cough, especially without or but on slight exertion, and not accompanied by evidence of pulmonary edema, is, I believe, one of the most important symptoms. The edema itself is of course not grave, but if it is removed longer intervals of comfort may be secured. Occasionally the socalled *èdeme à bascule,* or seesaw edema, is noticed which changes from side to side according to the position of the patient. These attacks may be due to heart block or auricular fibrillation or flutter. Syncopal attacks are not uncommon and vary in intensity; the degree may be so great as to simulate apoplexy, without, of course, resulting paralysis. They may come on suddenly, independent of exertion, and resemble asthma or a continuous sense of suffocation, or, as already remarked, muscular exertion may be necessary to bring them into evidence.

Other symptoms are pale skin, mucous membranes bluish, and extremities cold, morale often depressed. Symptoms of venous distention are rare, except slight edema above the ankle; gastrointestinal symptoms and constipation are common, but dropsy is never present without dilatation, which, however, occurs in about one third of the cases. The amount of urine is apt to be diminished often to only one half or even one fourth the normal amount. A slight quantity of albumin and narrow hyaline casts may be present without kidney disease. The phenolsulphonephthalein test shows that the elimination is normal or but slightly decreased except in the primary renal group of cases, and more important the blood chemistry is normal or but little changed.

Hypertension is found in many, but by no means all, of these cases. Pulse pressure may be high. But in my experience hypotension is also to be dreaded. Both terms, however, are only relative ones and I have known several cases where the lowering of the systolic pressure below about 180 was attended by the return of pulmonary edema.

Coexisting degeneration of other organs often modifies the general character of the symptoms of fatty degeneration, but the existence of arteriosclerosis is no more pertinent to the diagnosis than the yellow arcus.

Fatty overgrowths rarely give rise to distinctive symptoms unless infiltration or fatty degeneration has supervened. Necessarily the heart sounds are less clearly conveyed to the ear than in health, but in these cases it has often seemed to me that after exercise the sounds become more distinct, while the contrary is likely to occur in cases of the degenerative form.

The determination of the function capacity of the heart is of great importance, but very difficult to estimate. Herz determines the pulse rate per minute and then causes the patient to extend and flex the right forearm without much muscular contraction for one minute. In the normal heart there is no change, but in the weak heart the frequency is reduced from five to twenty beats per minute. Shapiro counts the pulse first in the recumbent and then in the sitting position. In health the frequency should be increased from three to ten beats per minute, but in the weak heart there is an absence or diminution of this frequency. Barringer measures systolic blood pressure at intervals of thirty seconds after the cessation of varying amounts of work performed by raising dumbbells or a steel bar. He believes that if the curve formed by plotting these results, rises, i. e., if the systolic pressure reached the maximum not immediately at the cessation of work but from thirty to 120 seconds later, the work performed is overtaxing the heart. He believes that the amount of work just sufficient to produce such a blood pressure reaction may be used as a measure of the heart's functional capacity. Rapport, however, has shown that in normal individuals cessation of work is always followed by a rise in blood pressure, more or less proportional to the amount of work done. Pulse pressure determinations have proved of little value in the study of cardiac function.

I must express my regret that the röntgen rays are not more generally used in cardiac diagnosis. The use of the electrocardiograph is necessarily more limited, but there is no excuse for the limited use of the former. For some years past it has been my custom in teaching to have sections of the class present at the fluoroscopic examination and more recently in order to avoid the enlargement of the heart silhouette produced in the examination, I include the orthodiagraphic, or teleröntgen graphic methods for the excellent reason that I believe, and this notwithstanding the opposite view held by MacKenzie, that these are the most accurate methods of determining the size, shape, position and movements of the heart.

PROGNOSIS.

It is interesting to note that the negro mortality from one to five years and from thirty-four to fifty-six years is double that of the white, but the mortality in cases with severe cardiac pain in the white is increasing and is already double that of the negro. Up to twenty-four years the death rates of both white and negro females are higher than that of males, while later it is much higher for the males. Male Russian Jews show a peculiar liability to thromboangiitis obliterans. Eighty-five per cent. of the deaths after forty years and one fifth of all deaths are due to heart trouble.

Many patients die suddenly when the symptoms are either absent or not considered of sufficient importance to merit treatment; but too many cases of socalled heart failure with fatal termination are recorded in patients who have recently been under observation and in whom the condition was unrecognized. In most cases the outlook is most serious, but perfect recoveries of the parenchymatous fatty types after both acute and even chronic infections are everyday occurrences. And even in the cases accompanied by arteriosclerosis and dilatation much may be done to prolong life and render the patients comfortable provided they are made to recognize the important fact that they must cut down a varying but generally large proportion of their work.

TREATMENT.

The acute myocardial changes following infections are generally attended by a more or less persistent increased frequency of pulse rate, even while at rest, with a low blood pressure—approximately 90 systolic and 60 diastolic. A diminished pulse frequency in these cases can be accepted as a normal result.

Rest, followed by gradual exercise, is of main importance, with the exhibition of tonic doses of strychnine. In acute myocardial degeneration, which sometimes accompanies syphilis, the question arises as regards the use of Ehrlich's salts. Personally, I am inclined to believe that the administration of mercury, either hypodermically, by inunction, or by mouth, is the safer plan to pursue provided we subsequently obtain repeated negative Wassermann reactions. If this does not follow, or if, in the rare instance, mercury cannot be given—as in a case of malignant precocious syphilis that I reported—comparatively small doses of the older salt should be given in preference to the new, and of course the subsequent use of mercury. These remarks apply with equal force to the cardiac cases which develop in the later stages of lues, with the addition of the iodides, which are often very useful.

In the chronic forms sufficient exercise should be permitted, short of producing heart strain—alternating, if necessary, with periods of rest in bed. This can only be determined by a careful study of the individual case. All excesses are of course to be avoided. The food should be restricted to the necessary caloric value; meat diminished, and cooked in such a manner as to be most digestible. It is to be remembered that acute indigestion may cause death through the crippled heart. Liquids should not be taken in large quantities.

Attention to the condition of the bowels is of importance—the regular use of an afterdinner pill, or an occasional mercurial purge followed by a saline, alternating from time to time with high rectal irrigation. In persons of overweight the restriction of the use of fats, starches and sugars is often sufficient to cause a reduction and improvement of symptoms. Massage and medical gymnastics are especially useful in these cases.

The Oertel and Schott treatments are also useful in selected cases, and can be carried out at home with a trained attendant.

Digitalis, digalen, digipuratum and strophanthus are useful in the dilated group, but are to be used with high tension. I frequently add tincture of aconite to one of these preparations with satisfactory results. The intravenous method should be reserved for particular indications and extreme cases.

NITRITES.

Most useful is the soda salt, which can be associated with either aconite or digitalis. They can be given in larger doses than usually employed.

In the bradycardia group aromatic spirits of ammonia, fifteen minims every two or three hours, caffeine, and small doses of strychnine should be given.

Diuretin is useful in the edematous cases and may be associated with infusion of digitalis. Also the combination of calomel, digitalis, and squills.

Rather curiously there is a widespread fear regarding the use of morphine in these conditions. In my opinion it is one of our most useful drugs in the treatment of severe cases of heart failure, and I find that chloral hydrate is often more useful as a hypnotic than some of the newer preparations, such as barbital or veronal.

Venesection is useful in dyspnea due to threatening or existing pulmonary edema, particularly with dilatation of the right auricle, but it has no lasting effect in hypertension. It helps redistribute the blood and may cause an elimination of the water retained. If the hemoglobin percentage is below seventy it is contraindicated.

The amount of salt should be limited. Anemic patients should be given a fairly ample protein allowance, and kidney cases a diminished one. While in hypertension a diet of milk and vegetables should be recommended and the Karrell cure of twenty-five c. c. of milk to the kilo of weight is useful in fat subjects. Strong coffee and tea as well as much alcohol should be prohibited but on the other hand I know of nothing more useful in severe pain and asthma than cognac or whiskey and a good claret is one of the best appetizers and consequently blood makers.

In addition to massage respiratory gymnastics are useful. During inspiration the diaphragm is drawn downward with the result that there is an influx of blood in the chest cavity. Note the inspiratory collapse of the veins of the neck. At the same time pressure on the abdominal organs causes a rise in intraabdominal pressure as proved by swelling of the veins of the lower extremities, sometimes seen during inspiration. The patient is made to inhale deeply and to exhale in two steps in a cogwheel manner, twice daily, each time for a minute, with pressure of the hands against the lower part of the thorax.

In relaxed abdomens, particularly those with gastroptosis, an abdominal bandage is of great advantage, and I have some time found use for the heart bandage of Abbé (*Herstutze*).

Some Points in the Examination of the Heart for Life Insurance*

By FREDERICK W. PRICE, M. D., F. R. S., Edin.,
London,
Physician to the National Hospital for Diseases of the Heart; Senior Physician to the Royal Northern Hospital, London.

The examination of the heart is of special and enormous importance. In all probability the cardiovascular system is the most important of all in regard to life insurance, since the length of life of most individuals depends so largely upon the integrity of that system. The difficulty of the subject has been augmented by the increasing practice of accepting lives for reduced terms of years and with extra premiums. This involves the whole question of prognosis, admittedly a most difficult problem, which lies outside the scope of this article, but I may be permitted to say that the first essential for prognosis is an accurate diagnosis, especially with regard to irregular action of the heart and cardiac murmurs and their significance.

It is obviously impossible in the space at my disposal to deal with the whole subject of the examination of the heart for life insurance. I shall only attempt to deal with some of the problems which are the most common and of the greatest practical importance. I shall not, for example, deal with the subject of the history of previous illnesses, except to touch upon rheumatic infection of the heart in childhood. This is a subject of very great importance, and, notwithstanding the fact that the subject has, during recent years, received a great deal of attention, it is still not sufficiently realized how easy it is to overlook a rheumatic infection in childhood. In trying to elicit a history of such an infection, it is necessary to bear in mind the following facts: In children arthritis is often slight and may be even entirely absent, while affections of other parts are more frequent and constitute a more conspicuous feature of the disease. Thus, sometimes the affection is confined to the tendons or the fascia in the neighborhood of the joint, as, for example, the tendons of the hamstring muscles under the knee. Subcutaneous nodules, certain exudative erythemata, and purpura rheumatica are more frequent manifestations of the rheumatic infection. Chorea is a common indication. Tonsillitis is perhaps more commonly of rheumatic origin in childhood than in adult life. Lastly, cardiac involvement is a much more frequent manifestation of the rheumatic infection in children than in adults; it is at least as frequent an indication of the rheumatic infection as any other and should not be regarded as a complication; and it may occur in association with any of the foregoing, or with an indeterminate febrile attack, or alone, that is, it may be the only manifestation of rheumatism. Another point to bear in mind is that while endocarditis may occur acutely in children, as in adults, it often occurs in a subacute and insidious form, there being not infrequently a total absence of subjective symptoms, or, when these are present, they are often masked by other manifestations of the causal infection. It ought also to be remembered, with regard to rheumatic infection of the heart, that, when there is a clear or suspicious history of acute or subacute rheumatism, an apical presystolic murmur and a short sharp first sound at the apex, indicative of mitral stenosis, may not make their appearance until some years after the onset of the rheumatic infection, and that the appearance of an aortic diastolic murmur, signifying aortic incompetence, may be delayed, though not to so great an extent.

IMPORTANCE AND SIGNIFICANCE OF SUBJECTIVE SYMPTOMS.

The question of subjective symptoms in a person applying for life insurance is of great importance, for the following reasons: It is agreed that the essential cause of heart failure lies in the heart muscle, and if this view be correct, valvular defects, arterial disease, and disturbances of the cardiac mechanism —such as auricular fibrillation—should be regarded not so much as specific affections in themselves as from the point of view of the relation which they bear to the myocardium. Take the case of a valvular lesion. First of all, it can be readily understood that it is a mechanical disadvantage in the work of the heart muscle. But it should also be remembered that there are, as a rule, along with the valvular lesion, coincident changes in the cardiac musculature, the coronary arteries, or the aorta.

In all cases of valvular disease, therefore, it is of the utmost importance that we should endeavor to ascertain whether the lesion which has invaded the valve has also affected the myocardium, or the bloodvessels, or both. These morbid changes in the musculature of the heart may occur as an acute condition, which later on may become chronic; or they may occur as a primary chronic condition, as a result of degenerative changes. As an example of the former, an acute infection of the mitral valve by the

---

*Read at a meeting of the Life Assurance Medical Officers' Association, London, January 4, 1921. The substance of this paper was published in a recent issue of the *Lancet*.

rheumatic poison may be cited. It is recognized that this is usually followed by organization, resulting in the formation of fibrous tissue, which tends to contract as life advances, ultimately giving rise to permanent stenosis, or incompetence, or both. It is also known that in every case of acute endocarditis there is probably always present some degree of myocarditis, and that acute myocarditis may occur independently of acute endocarditis. But it is not sufficiently understood that acute myocarditis is often followed by permanent structural changes in the myocardium, which, as in the case of endocarditis, may not fully declare themselves until some years afterwards, and we should always endeavor to ascertain the degree of these permanent structural changes. As an example of a primary chronic affection, resulting from degenerative changes, most cases of aortic incompetence which come on insidiously in males during or after middle life may be cited. As a rule there are coincident or secondary changes in the cardiac musculature, aorta, or coronary arteries, and it is our duty to endeavor to estimate the degree of these changes. Another point of importance is whether the lesion—be it the result of a previous attack of acute endocarditis, or primarily chronic due to degenerative changes—is progressive or not.

Now, with regard to the investigation as to whether the myocardium is involved or not, and if so to what extent, and whether the lesion which is present is progressive or not, while the results of physical examination—such as the size of the heart—are important, the most important question of all is that of the functional efficiency of the heart. Is this impaired, and, if so, to what extent, and is the degree of impairment increasing? Mackenzie has emphasized the view that the best way to answer these questions is to ascertain how the heart responds to effort; in other words, the amount of physical exertion in which the patient can indulge without experiencing symptoms of cardiac distress. It is, therefore, easy to understand the vital importance of ascertaining this.

I can fully appreciate the difficulty of the problem in the case of a person applying for life insurance, if for no other reason than the unfortunate fact that neither the examining room of a life insurance office nor the consulting room is always a Temple of Truth. Nevertheless, I would respectfully urge that some such question as, Do you experience shortness of breath, palpitation, fatigue, giddiness, faintness, precordial discomfort or pain, or a sense of pressure or tightness across the chest during or after considerable or moderate exertion? should be included in the examination form and put to each applicant for life insurance, and that a searching inquiry should be made, and also that some simple exercise test should be performed.

In conducting this inquiry it is essential at the outset that three facts should be borne in mind. The first is that the natural standard of the heart's strength varies in individuals, each individual knowing the kind and amount of exertion in which he can normally indulge without producing symptoms of cardiac distress, and being aware when there is a departure from this, and to what extent. Our inquiry should aim at finding out whether the normal standard of an applicant has decreased, and if so, to what extent, and whether it is still decreasing. The second fact which should be borne in mind is that symptoms of cardiac distress on exertion may be due to causes other than heart disease. Thirdly, the cardiac muscle may be merely temporarily exhausted, and this may occur whether the heart is diseased or not. But, provided extrinsic and temporary causes —such as anemia, sleeplessness, temporary physical or mental overstrain, and deficient tone due to lack of physical exercise—can be excluded, the fact of a departure from the normal standard of an individual, and its degree, may be taken as fairly indicative of the presence and degree of myocardial disease. Further, if the symptoms of cardiac distress on exertion are increasing—in spite of an adequate period of rest and the employment of other remedial measures—and provided again that we can exclude extrinsic and temporary causes to account for this, we may be satisfied that the lesion is progressing, and its rate of progress may be inferred by the rate of increase in the severity of the symptoms.

Passing to a consideration of the respective value of the various subjective symptoms, breathlessness is one of the earliest and a very important symptom, and the amount of exertion which the patient can undergo without becoming breathless is of great value in estimating the state of integrity of the heart muscle. It should be remembered, however, that it is a symptom common to many affections beside heart disease, such as anemia, pulmonary affections, and displacement of the contents of the abdominal cavity.

By palpitation I mean the consciousness of the cardiac impact against the chest wall, and with this there is frequently, but not always, an increase in rate. The term, as used here, does not include the sensations which may be present in extrasystoles, auricular fibrillation, auricular flutter, or paroxysmal tachycardia. While palpitation may occur in organic disease of the heart, it should be remembered that it is probably more frequent and most characteristically met with apart from organic disease.

A sense of exhaustion during or after physical or mental effort is a common symptom. Cerebral symptoms, due to a diminished supply of blood to the brain, may depend upon cardiac causes, especially aortic disease and myocardial degeneration. Among these symptoms are giddiness, syncope or fainting attacks, attacks closely resembling petit mal, lack of power of concentration, and early fatigue on mental effort. It should be noted that the attacks of giddiness so frequently complained of in old people have no necessary relation to organic heart disease.

While syncope may, and frequently does, occur in heart disease, it is probably as frequently due to some temporary functional derangement, being not infrequently the result of vasomotor instability. Attacks closely resembling petit mal may occur in elderly people, especially in those with arterial disease and myocardial degeneration, and in the early stages of heart block, and it is sometimes extremely difficult to distinguish them from fainting attacks. The latter are, as a rule, preceded by a preliminary sensation of great weakness, giddiness, loss of sight, and, it may be, nausea and vomiting, while during an attack the face becomes of a greenish pallor, the patient breaks out into a clammy sweat, respiration almost or completely ceases, and the pulse at the wrist is feeble or even imperceptible; the return to consciousness is gradual.

Pain in the precordium is a frequent symptom of heart disease. The most characteristic feature of pain due to heart disease is that it is brought on by exertion, though it should be noted that the pain may not come on until some hours after the exertion which has induced it. The site of the pain is frequently in the neighborhood of the apex beat, but it may be complained of over any part of the precordial area. The pain of angina pectoris, on the other hand, is almost always over the sternum, a point which I shall refer to later. The pain in heart disease may be constant, dull, and aching; or recurring and sharp; or may present the characteristic features of angina pectoris. While pain in the precordium may occur in organic disease of the heart, it should be remembered that it is also frequently met with apart from this, especially in females. A constant, dull and aching pain is of greater diagnostic value than a sharp recurring pain, usually indicating a tired heart. Accompanying pain in the precordium, or occurring independently of it, there may be a sense of oppression or tightness across the chest, and tenderness in the precordium may also be associated with it.

Angina pectoris is not rarely missed. While the term is usually employed to denote a paroxysmal attack of pain in the region of the heart—the paroxysmal nature of the pain being its characteristic feature, with a tendency to radiate in certain directions, and being accompanied by a feeling of constriction within the chest and a sense of impending death, it should be remembered that this description is that of a typical and severe attack, and there are many grades and modified forms of this affection. For example, on physical exertion or emotion, there may be only a little discomfort or pain felt over the sternum, radiating to the arm and neck, and accompanied by a feeling of uneasiness and distress, which may at first disappear as soon as the exciting cause ceases, but at a later stage may continue for some time after its cessation. Will you allow me to emphasize the fact that the pain of angina pectoris is almost always over the sternum. Less frequently it is on one side of the chest or the other, usually on the left side. I have seen a number of cases in which the pain was strictly limited to the epigastrium, and some had been diagnosed as cases of dyspepsia, because the patient had told his medical practitioner that the pain occurred after food; but, on further inquiry, it was not difficult to elucidate the fact that pain after food occurred only when physical exertion was indulged in. The pain in angina may also begin in the left arm, or the jaw, or the left pectoral muscle, or even in the left leg. The fact that the pain at first occurs during or after exertion is of fundamental importance with regard to diagnosis.

Lastly, with regard to subjective symptoms, it is necessary to distinguish between those due to septic infection—as, for example, from the teeth, the tonsils, or the bowel—and those due to organic heart disease. In the former, the most prominent symptom is a sense of exhaustion after effort. There is frequently a sense of depression, often accompanied by irritability of temper, and of giddiness and faintness, which may disappear on lying down, and vasomotor instability in varying forms is often a marked feature; and when palpitation and precordial discomfort or pain are complained of, they frequently have no relation to exertion. In the case of subjective symptoms due to organic heart disease, on the other hand, the nervous and vasomotor symptoms are little, if at all, in evidence, the earliest subjective symptoms are primarily cardiac, of which breathlessness, palpitation and precordial discomfort or pain are the most prominent, and they usually arise as a result of effort.

PHYSICAL AND INSTRUMENTAL EXAMINATION.

We will now pass to a consideration of some of the results to be obtained by physical and instrumental examination, and we will first deal with the arterial pulse.

Rate of the pulse.—May I at the outset suggest that in each case the pulse should always be taken both at the beginning and at the end of the medical examination. May I also emphasize the importance of bearing in mind the fact that the rate of the radial pulse does not necessarily represent the ventricular rate, for not infrequently in irregular action of the heart many beats are so feeble that the pulse waves do not reach the wrist (Fig. 1); the ventricular rate should, therefore, be counted at the apex, either by palpation or auscultation, preferably the latter. While the normal rate of the heart is about 72 a minute, it should be remembered that it has a considerable range of variation in perfectly healthy individuals; in some it is always above this average, and has been known, although very rarely, to average 120 a minute, whereas in others it is always correspondingly infrequent. It is difficult, therefore, to decide when an increase of the cardiac rate in an individual is pathological. In this connection, a record of the past history is of value.

Among the causes of the pathological form of tachycardia, other than the various forms of heart disease, I would mention the excessive use of alcohol, tobacco, tea and coffee, septic absorption from the teeth, the tonsils, or bowel, and pulmonary tuberculosis. The increase in the rate of the pulse when an individual assumes the upright posture after lying down is normally not more than at the most 20 a minute. Anything above this is especially suggestive of vasomotor instability. The increase in the rate of the pulse induced by physical exertion varies in healthy individuals; it may be marked on severe physical exertion, even when the individual is in training, and not infrequently the rate is increased up to 120 or even 140 a minute on even moderate physical exertion. It is, therefore, difficult here also to determine whether an increase in rate is pathological. In this connection, the presence or otherwise of accompanying subjective symptoms of cardiac distress is of fundamental importance. The time which may elapse before the pulse rate returns to the normal after exertion is of greater diagnostic significance.

(*To be concluded.*)

Editorial Articles

PURGATION

Dr. Pedro of Rio Janeiro has called attention to the dangers of indiscriminate purgation. He mentions the fact that, a century ago, not only were purgatives in routine use but also emetics and bleeding. Doubtless the emetics were sometimes, perhaps often, needed by our ancestors who surpassed us in the art of stuffing themselves. Purgatives would seldom be needed were there more care of diet and defecation, but as we, of our era, are notoriously careless about both, these drugs still find a place of the highest prominence and usefulness.

Nevertheless, it is high time that attention was called to the too frequent and the routine use of purgatives, for these drugs are by no means without their dangers and are certainly not to be used in any case for the mere sake of giving something. Perhaps purgatives are most abused in hospitals, where, alas, their administration to the new arrival proceeds with the certainty of the laws of the Medes and Persians. It matters not if the patient's life hang by a thread which a vigorous cathartic may sever, or if he has been physicked without end before entering the institution, he gets his ten grains of calomel, or its equivalent, just the same. We have seen more than one victim of pneumonia work himself to extinction over the bedpan.

Time was when every patient to be operated upon must be purged just previous to the ordeal, even if sent in by a physician who had already castor oiled the patient to the limit. How some of those who have been operated upon under such conditions have survived is a mystery.

The routine use of purgatives in digestive disturbances which are due to constipation, does not, of course, cure the condition. As Dr. Pedro remarks, it is the easy thing to do and, we fear, we are all inclined to do the easy thing. It is certainly troublesome to go into all the details of instruction in the habits which a patient must acquire in order to rid himself of faulty functioning of the bowels.

It is something of a shock to learn from Pedro that the use of purgatives in food poisoning is not beneficial. At any rate, in a group of twelve cases, which he cites, those treated without catharsis did much better than those who were purged. Pedro also believes purgatives do more harm than good in uremia. This may seem an extreme statement, but should cause us to think over the matter. In many acute conditions accompanied by fever, the immediate fall of temperature attributed to the action of a cathartic is deceptive, as this is due to general depression from the drug, and the temperature again rises when the result of purgation passes.

To return again to the subject of constipation, and especially in children, the physician who gets the young mother into the way of depending on food, water, and daily habit, instead of upon the bottle of laxative, helps the family to which he ministers, not only physiologically but economically, for the sum paid for patent bowel movers is something astonishing.

CARDIAC ACCIDENTS OF THYROID ORIGIN

Tachycardia is a symptom in Basedow's disease which undergoes considerable variations. Among the paroxysmal tachycardias met with in this morbid process there are two principal types, namely, auricular tachysystolia, which consists of a considerable acceleration of the auricular contractions—about three hundred—while those of the ventricle average about one hundred and fifty, and a total disorder of the ventricular contractions in their relation to fibrillation of the auricles. The permanent tachycardia of exophthalmic goitre is normotropic with paroxysmal attacks, but occasionally it may be complicated by heterotropic crises, a notion of importance in the study of the latent symptoms of Basedow's disease.

It was formerly supposed that the blood pressure was below normal, but recent researches—those of Lian and Gallavardin in particular—have shown that hypotension is uncommon and that a slight hypertension usually exists.

From the viewpoint of pathogenesis, as well as the genesis of the disturbances of the cardiac rhythm and hypertension, careful attention should be given to hypertonia of the sympathetic which is always constant in exophthalmic goitre. Hypersympathicotonia with or without hypervagotonia would seem to result from a toxic nervous impregnation. These patients are autointoxicated by the abnormal products of thyroid secretion which act on the heart, impregnating in turn the cells of the myocardium. These data explain the mechanism of the asystolic accidents occurring during the evolution of Basedow's disease and which appear to be quite independent of any valvular lesion. The cardiac exhaustion is the consequence of both hypersympathicotonia which overworks the heart and the autointoxication inherent in the disease which poisons and causes changes in the cardiac musculature. Asystolia is all the more prone to occur when rheumatismal or syphilitic valvular changes previously exist. Thus can be explained various systolic murmurs detected in exophthalmic goitre and have been variously interpreted.

Orthoradioscopic investigations have confirmed what clinical researches have already taught us. The aorta is frequently involved in exophthalmic goitre, presenting a certain degree of dilatation and occasionally a distinct aortitis can be detected. Lian has shown that there is often a cardiac hypertrophic dilatation, first of all present in the left ventricle.

The latent symptoms of exophthalmic goitre are characterized by the attenuation or even absence of ocular and thyroid manifestations and predominance of cardiac disturbances, these usually being a permanent tachycardia, with or without paroxysmal crises. Ovarian insufficiency causes the largest number of these latent conditions. To make a diagnosis of the latent syndrome of exophthalmic goitre one must also discover one or two thyroid or ocular signs of the disease as well, especially the latter. Graefe's sign is, according to Attler, found in twenty-one per cent. of the cases, Stellweg's sign in sixty per cent. Hyperesthesia of the thyroid region—first described by Lian in 1918—should be looked for, although it is rare.

Laboratory researches are of little avail in the diagnosis. Kocher's hemoleucocytic formula is not to be relied on. The adrenalin test does not prove that the symptoms are due to the thyroid. An increase of metabolism, according to Dubois, from twenty-one per cent. to seventy-five per cent., is seen in latent exophthalmic goitre, so that treatment directed against this disease may reveal the true nature of the symptoms presented by the patient.

In myxedema and mild hypothyroidea, hypotension with clinostatic tachycardia and acrocyanosis represent the cardiovascular symptoms. The hands are cold and blue, the pulse small, weak and hardly perceptible. In other words, phenomena inverse to those present in hyperthyroidea are met with. The administration of thyroid preparations will give excellent results in these cases.

In ordinary goitre there are three toxic cardiac processes, viz., thyroidopathic cardiac hypertrophy giving rise to disturbances of variable intensity, the thyrotoxic goitrous heart strictly speaking, with accentuation of the cardiac disturbances, and lastly, the torpid goitrous heart. In the latter form all the symptoms of Basedow's disease may develop in a case of long standing goitre, an eventuality that should be recalled in all forms of goitre having a slow evolution.

NEW YORK'S HOSPITAL BED CAPACITY

The results of a study of the files of the Division of Institutional Inspection, made by Dr. C. E. Banker, are published in the January number of the *Monthly Bulletin* of the New York City Department of Health in an article entitled Hospital Bed Capacity of New York City. Doctor Banker states that all institutions in the city which may reasonably be classified as hospitals have been included in the study, with the exception of certain institutions that have ceased operation during the year, organizations that have torn down their hospital structures with the intention of rebuilding and, for this reason, are at present not receiving patients, and a small number of institutions that harbor sick or convalescent children for a few months during the summer, but maintain no service during the colder months of the year. "While the Department of Health takes a broad view," writes Doctor Banker, "of what constitutes a hospital, and the hospital bed capacity of the city, the beds in institutions other than hospitals which are set aside for isolation purposes, and those set aside by institutions for the care of their own inmates, and those maintained in institutions outside the city limits, are not included in the figures presented. . . . It must be remembered, however, that they are true for the present only, for new organizations are being formed and new hospitals erected, old hospitals are closing their doors for one reason or another, and the hospital bed capacity of the city is continually in a state of flux. The figures here presented we believe to be unusually accurate and up to date, for they are based, almost exclusively, on a questionnaire sent out by the Division of Institutional Inspection, within the past month, and the population figures are those of the Department of Health estimate for October 31, 1922."

These data show that, at present, Greater New York has, within its limits, 216 public, semipublic, and private hospitals to care for those of its population of 5,896,124 that may need hospitalization. In these institutions are 44,793 beds for the reception of patients. This makes an institution for every 27,125 persons, and a bed for every 131 persons. Classified by type of hospital, the figures are: for the twenty-five public hospitals of Greater New York, 24,288 beds; for the 121 semipublic hospitals, 18,767 beds; for the seventy private hospitals, 1,738 beds. On the basis of a broad classification, the various special hospitals of the city gave the following figures: for women and children, including maternity hospitals, 3,680 beds; for mental and nervous cases, including mental defectives, 10,523 beds; for cancer and allied diseases, 201 beds; for contagious diseases, 2,317 beds; for incurable and chronic cases, exclusive of tuberculosis, 1,613 beds; for tuberculosis, 2,435 beds; for treatment of diseases of the eye, ear, nose, and throat, 689 beds; for orthopedic defects, 435 beds; for the national public health service, and the care of the soldiers, sailors, and marines that may be within our gates, 3,088 beds; for convalescents and those on special diet, eighty-eight; for diseases of the digestive system, fifty-one; for the special study of selected diseases, sixty. This makes a total of 25,180 beds. If we subtract these from the total bed capacity of the city, the balance, 19,613, represents the bed capacity of the general hospitals of the city, but in this case also the term general is a loose one.

Two classes of patients have most meagre accommodations—convalescents and mental cases. The former because provision for them in the hospitals of the city is very limited, their beds are needed for new acute cases, and the hospitals, in cases of free or part pay patients, are relieved by their discharge of the not inconsiderable expense of their care. Provision for the care of mental cases is extremely inadequate and limited in the city. Dr. Banker's conclusion is that "except for the two groups mentioned above, and, possibly, the group for chronics and incurables, where there appears to be lack of beds for those able to pay in part for their care, the city seems to be fairly well provided with hospital bed facilities at the present time."

THE HEALTH ORGANIZATION OF THE LEAGUE OF NATIONS

Among other articles that have appeared recently in leading periodicals, giving accounts of the work of the comparatively little known health activities of the League of Nations, are one by Dr. Wickliffe Rose, general director of the International Health Board of the Rockefeller Foundation, in the *Review of Reviews,* entitled Epidemic Control in Europe and the League of Nations; and The Health of Nations, by Gertrude Seymour, in the *Medical Woman's Journal.*

The aim of the Health Organization of the League of Nations may be stated as the correlation of the activities of national public health administrations. It seeks to initiate action which cannot be undertaken by a single administration, and, in times of emergency, to aid national administrations, but not to assume permanently national responsibilities. Hence, it is by nature both advisory and executive. Also, it is essentially a technical organization, with a highly specialized field of action, hence the principles upon which its actvities are based have been formulated by specalists in public health, and its membership has been chosen, not according to political, but according to professional standing. As a technical body, it is composed of a committee, a secretariat, and a consultative conference. The committee is composed of sixteen members prominent in the public health activities of thirteen countries and of three international societies. The one woman member of the committee is Dr. S. Josephine Baker, vice-chairman of the child hygiene section of the American Public Health Association, and director of child hygiene in New York City. The secretariat is composed of a director and staff, with headquarters at Geneva, who execute the decisions of the Health Committee. The director is Dr. Louis Rajchmann, who was chief of the Polish Health Service during the war. At the beginning of the current year, Dr. Edgar Sydenstricker, of the U. S. Public Health Service, was put in charge of the work in epidemiology. The consultative conference of the organization is at present supplied by an unofficial voluntary cooperation with the Office International d'Hygiène Publique.

Miss Seymour, in her article in the *Medical Woman's Journal,* gives an admirable outline of the program laid down by the specialists composing the health organization: "They advised that the International Health Organization should advise the League of Nations in matters relating to health; bring the administrative health authorities of all countries into a closer relationship of acquaintance, communication, and confidence; effect a rapid exchange of information regarding diseases, especially as these threaten to spread from one country to another, so that immediate precautions may be taken; aid in concluding or revising international agreements and ascertain how such conventions are being made effective; cooperate with the Labor Office in matters of industrial hygiene, and with the League of Red Cross Societies and other international voluntary societies, in health matters of international concern, and to send missions on public health questions when desired by a country to do so."

Among specific practical applications of this program, the following activities may be mentioned. Work in controlling epidemic conditions has been carried on through the health administrations of both the larger and smaller states adjoining Russia, contributions from the former having not only made their own territories safe from disease, but helped the feeble governments of the lesser states to cope with it and to establish sanitary, preventive conditions. This work, originated in Poland, has extended to Ukrania, Latvia, Lithuania, and Russia. Epidemic conditions and methods for their control are being studied in the ports of the Far East. A special tour of the refugee camps of the Near East has recently been made. In response to a call from Athens, a representative has been sent to Greece to cooperate in the supervision of the refugee camps there. Special studies and surveys are also being carried on relating to drug traffic and control, venereal disease control, sleeping sickness in Africa, and tuberculosis. Important work is being done in regard to revising the International Sanitary Conventions of 1912. Valuable reports have been made as results of surveys of disease conditions in various countries, among them six on epidemic and famine conditions in Russia. Several conferences of note have been held for exchange of ideas and opinions through lectures, papers, and discussions, and through inspection of institutions. The Rockefeller Foundation provides by gift for such interchange and conferences.

Surely the recital, which is the briefest outline, of such accomplishments in promoting international health is enough to justify to an extent at least the effort to correlate national interests which affect the interests of the human race as a whole under standards of world wide benefit and physical, mental and moral health—even though the idea of world peace, which would eventually be one of the results of such international cooperation, seems to be a subject for discredit and derision only to a certain type of American politician.

THE MENACE OF DRUG ADDICTION

The medical practitioner who has his eyes open knows how prevalent and widespread drug addiction is in the United States. He sees the wrecks which are being produced and the potential criminals which are being daily created. If he stops to think, he must realize how seriously public safety is thus threatened and how gravely civilization is menaced by this wave of international narcotism.

While it is true that relatively few of the thousands of miserable habitues have been produced by medical carelessness or criminal drug pandering by physicians, the medical profession is not wholly without blame. Modern chemistry and therapeutics and the laudable but sometimes mistaken desire to prevent or relieve pain have opened a veritable Pandora's box and an incalculable amount of harm has been done. The time has come when the medical profession must subject itself to the most rigorous regulation in order that not a single grain of heroine, morphine or cocaine is ever prescribed and that it be administered only to meet a proved therapeutic necessity. By this means only can we expiate the tremendous sin to which we have been innocently contributory. Those physicians who have so prostituted their holy calling as to lend it to the continuance of these destructive and debasing habits must be summarily estopped from further practice and forever banned from association with decent practitioners.

Here is a mental pestilence which is claiming its victims in all walks of society, creating a vast army of addicts which is largely composed of young men and women but which does not disdain youths and children. Eventually it leads to mental, moral and physical death. It is an archproducer of crime, a corrupter of the legal machinery of government and a ravaging destroyer of the very foundations of society. Its ultimate source is greed, the avarice which traffics in the bodies, minds and souls of humankind. The production and sale of habit forming drugs is one of the most profitable businesses known to man. To carry on this nefarious trade, enormous organizations backed by tremendous amounts of capital have been formed and from the poppy fields of Turkey, Persia and India and the coca groves of South America and Java their sinister operations extend into the very heart of American life. Bribery and corruption, deceit and smuggling, bestiality and murder are the agencies by which this traffic runs through the chemical works of England, France, Germany and the United States, through the ports of the world and the distribution centres to the horde of criminal drug venders and their weak dupes. The Harrison Act is only a puny preventive while the Miller Act, excellent law though it be, is powerless without adequate appropriations. The dope ring is well entrenched; it is organized with hellish ingenuity; it is provided with much money. Only the most strenuous national and international efforts will tear it up by the roots. Sordid greed is not easily controlled.

As a profession, we must purge ourselves of our dope peddlers, a band of ravening wolves parading as ministers of healing. We must make sure that our hospitals, asylums and corrective institutions are protected against invasion by soulless narcotic sellers and that there are a sufficient number of sanatoria for the salvaging of addicts. As citizens, we must see to it that there is an open season for all illegitimate drug venders. We must insist on the thorough enforcement of the Federal, state and local laws which aim at the control of habit forming drugs. These are not prohibition laws, neither are they revenue acts, these are measures for the protection of the public health and should be administered as such only. The public should be well taught the horror of drug slavery.

But these only scratch the surface. The great underlying cause must be logically attacked. Freedom from the curse of heroinism, morphinism and cocainism will only come by adequate control at the source. There is little difficulty in checking up banknote paper so that not one square inch is lost from the first step of its manufacture to the point where the citizen receives it as legal tender. Similarly, there must be absolute control of all narcotics from the source where the raw products are grown, up to and including the point where they are administered by the physician to relieve a well recognized condition. We must not prate about interference with the rights of medical practitioners. If we are honest in our desire to get rid of this deep rooted evil we cannot logically object to the complete regulation of the administration of these dangerous preparations.

These things can only be brought about by concerted international action. The League of Nations is striving to work out a plan for the international combat and control of the habit forming drugs. Our observers at the meeting now going on should be given greater latitude in aiding in this movement. Surely there can be no political significance in our active participation in what is entirely a great international health movement. If America does not actively cooperate, a complete victory will not be achieved and we will suffer in exact proportion to the extent that we evade this serious responsibility. A dangerous situation confronts us; we must ruthlessly attack it.

ENLARGED RINGS

Probably no disability is causing the industrial surgeon and the employer so much annoyance as hernia. Where an examination can be made before engaging a workman the matter is simplified to some extent, though in the ruling of certain states claims for compensation can be made on a hernia that was known by all parties to exist at the time of employment, on the ground that it was made worse by the labor in which the man was engaged.

The whole subject of hernia and of the connection of hernia with occupational trauma needs a thorough study and the getting rid of much that is groundless tradition in the literature. The question as to whether hernia is produced frequently by occupational stress has by no means been proved. A few years ago someone hit upon the idea of determining the possibility of future hernia by digital examination of the external rings. It was a happy thought, or at least was so considered, but such examination has proved practically worthless.

That such examination could be of value is negatived by second thought as well as by the proof from experience. A hernia never begins at the external ring. It begins at the internal ring, which cannot be reached by the examining finger, or it comes through structures lying directly behind the external ring, with which the ring has little, or nothing, to do. The size of even the internal ring is of comparatively little moment, for the bowel is so extremely thin and moldable that a bit of gut of pinhead size presenting against it directly, would quickly, work its way through, just as a bladder filled with water can readily be pushed through the keyhole of a doorlock.

Hernia is a congenital affection due primarily to the assumption by man of the erect position with the consequent disarrangement of the muscles and fascia of the inguinal region as they are so nicely built in our quadripedal ancestors. The structural conditions must be more or less imperfect or it does not occur, but the mere size of the external ring is far from being a prophetic guide as to its future occurrence. Some more certain sign must be sought.

CHILD LABOR STATISTICS

The returns of the Census Bureau show that the proportion of gainfully occupied children ten to fifteen years of age in the United States was markedly reduced from 1910 to 1920. In 1910, the number of boys engaged in gainful occupations was 1,353,139, or 24.8 per cent.; of girls, 637.086, or 11.9 per cent. of the total number of children. In 1920, the number of boys was 714,248, or 11.3 per cent.; of girls, 346,610, or 5.6 per cent. of the total number of children. A table of the occupational groups shows that the largest decrease was in agricultural pursuits, amounting to 785,119 children. The reductions for all other occupations combined amounted to only 144,248. This great decrease of the number of children in the agricultural group is thought to have resulted from the shift of the census date from April 15th, in 1910 to January 1st, in 1920. The decrease in the number of child workers in mines and quarries is reported as being largely due to additional legal restrictions of such employment. Both these reasons affected other groups to some extent. In general, it is said, the decrease for children was but a part of a corresponding general decrease for all persons.

Obituary.

Dr. Wilhelm von Röntgen.—The famous discoverer of Röntgen rays died in his seventy-seventh year at his home in Munich. In 1895 Dr. Röntgen made his great discovery of Röntgen rays or x rays, and in 1900 he received the Nobel prize for physics, the same year in which the first Röntgen Ray Congress took place in Paris.

Dr. Röntgen received the Rumford Medal of the Royal Society in London in 1896. He also made investigations of value in other branches of physics including elasticity, capillarity, the conduction of heat in crystals, and the absorption of heat rays by different gases.

News Items

Dr. Lieb Advancement.—Columbia University announces that Dr. Charles C. Lieb has had advancement in grade from associate professor to professor.

Dr. Garretson Resigns.—Dr. William V. P. Garretson has resigned as attending neurologist to the Reconstruction Hospital, Central Park West and 100th Street.

Dr. Arthur I. Blau Returned.—Dr. Arthur I. Blau has returned from his pediatric work abroad and is now practising his specialty at his new office, 815 Park Avenue.

Eleventh Harvey Lecture.—Dr. Karel Frederik Wenckebach, professor of medicine, University of Vienna, delivered the eleventh Harvey Society Lecture at the New York Academy of Medicine, on Saturday evening, April 28, 1923. His subject was The Rhythms of the Heart.

Pittsburgh College Annual Dinner. — The Pittsburgh College of Physicians will hold their annual dinner known as the Second Bedford Lecture, on April 26, 1923, at 6:30 p. m., at the Duquesne Club, 325 Sixth Avenue, Pittsburgh, Pa. The essayist for the evening will be Dr. Sydney R. Miller, of Baltimore, Md., and the subject will be The Future of Our Profession.

Distinguished Japanese Physicians Visit State Health Department.—Three members of a party of distinguished Japanese scientists now visiting the United States under the auspices of the Rockefeller Foundation are spending a few days in Albany in order to study the work of the State Department of Health, including especially the State Laboratory, to which the visitors are giving an entire day.

Final Lorenz Clinic.—Dr. Adolph Lorenz gave his final public clinic of a series that he has held at the Health Department headquarters, 505 Pearl Street, recently. Sixty patients were examined, most of them children. Dr. Lorenz was assisted by Dr. Franklin B. Van Wart, orthopedic surgeon of King's County Hospital, Brooklyn, and by Dr. Thomas Martin and Dr. I. Cohn, of the Bureau of Child Hygiene of the Health Department.

Brooklyn Diagnostic Society Session. — The Brooklyn Diagnostic Society will hold its twenty-seventh session on Monday evening, May 7th, at 8:45 p. m., at the Institute Building, 867 St. Marks Avenue, Brooklyn. Program: Blood Transfusion, a Motion Picture Demonstration of the Author's Method, by Dr. Lester J. Unger, New York, and Carcinoma of the Breast, by Prof. John F. Erdmann, New York. Discussion. Dr. J. Gutman, chairman; Dr. Samuel S. Markell, secretary.

Mount Sinai Hospital Medical Board Holds Memorial Meeting.—The Medical Board of the Mount Sinai Hospital held a memorial meeting in the Blumenthal Auditorium, 1 East Ninety-ninth Street, on Monday, April 23, 1923, at 8:30 p. m., in appreciation of the work and influence of Dr. Arpad G. Gerster. The speakers were Dr. L. S. Pilcher, on Dr. Gerster's Services to Surgery in America; Dr. Howard Lilienthal, on Dr. Gerster as Teacher and Hospital Surgeon, and Dr. B. Sachs, on Dr. Gerster as Man and Scholar.

Cleanup Week in Virginia.—The week of April 16th has been set aside as cleanup week by the Virginia Board of Health. Information along health lines may be secured by writing to 1110 Capitol Street, Richmond, Va.

Tuberculosis Decreases.—The death rate from pulmonary tuberculosis in Nassau County showed a decrease of 17.3 per cent. in 1922 compared with the rate for 1921, according to figures issued by the Nassau County Sanatorium. The figures also show that there has been a decrease of 31.6 per cent. since 1919. This is contrasted with the decrease in United States registration area as a whole, which was only three per cent.

Smoking Beneficial. — Dr. E. P. Roger, of Paris, has carried out a series of experiments in which he claims that nicotine is not so dangerous as we hitherto have been given to understand. Having taken ten grams of ordinary French caporal tobacco, Dr. Roger extracted all the nicotine, producing a liquid which was sufficiently poisonous to kill a dog weighing sixty pounds. The doctor then took ten grams of the same tobacco and incinerated it under conditions similar to that of a pipe, producing a liquid which contained not only nicotine, but all the other chemical substances contained in tobacco. This liquid did not kill a guineapig weighing two pounds and produced no effect whatsoever on the intestines of a dog weighing sixty pounds.

Low Records in Communicable Diseases in 1922.—From the standpoint of communicable diseases the year 1922 was one of the most satisfactory in the sanitary history of the State, according to a summary made public by Dr. Hermann M. Biggs, State Commissioner of Health. Comparing 1922 with 1921, Dr. Edward S. Godfrey, Jr., Director of the Division of Communicable Diseases of the State Department of Health, reports declines last year both in the number of cases and in the number of deaths for most of the important communicable diseases, including typhoid fever, diphtheria, scarlet fever, measles, whooping cough, infantile paralysis, smallpox, and cerebrospinal meningitis. The number of cases of chickenpox and German measles also declined. On the other hand pneumonia and influenza were materially higher in 1922 than in 1921, though lower than in any other year since 1917.

Postgraduate Courses for Physicians.—Postgraduate courses for physicians of from ten to twelve weeks' duration will be given at the University of Göttingen, University of Frankfurt am Main, and the University of Leipzig during the summer of 1923. Modification in the period of the courses, and related matters, may be made to meet individual requirements. The courses will cover an intensive postgraduate study of all medical subjects, both theoretical and practical; the subjects will be generally selected by the applicants. Upon the conclusion of the courses duly authorized diplomas will be issued by the universities. Postgraduate courses at these universities can be arranged through the Academic Tours, Inc., Knickerbocker Building, 152 West Forty-second Street, New York.

LONDON LETTER

(*From our own correspondent.*)

London, *March 23, 1923*

ASIATIC REFUGEES A MENACE TO THE WORLD.

Conditions existing in Greece and Turkey at the present time are arousing alarm throughout the world. As a result of the Turks' victory the Greeks have been expelled wholesale from those parts of Turkey which had been made over to them by the Allies. Sir Patrick Hehiv, who went to Greece a short time ago to investigate the state of affairs, sent a report of his investigations to the *Lancet,* which was published in that journal on March 17th, last. He found that in Greece there were about one million refugees and that conditions could hardly be worse. In the *Daily Telegraph,* March 21st, last, there was published a report from Athens on the refugee situation in Constantinople prepared by Dr. Wilfrid Post, of Boston, the foremost medical authority in Eastern Europe, where for the past ten years he has been professor of medicine in Robert College, Constantinople College, and at the American Hospital, and is now on special service as medical director of American Near East Relief in its Constantinople refugee work, in which he is cooperating with Major McKinley and Major Hobson, of the British Sanitary Commission. Dr. Post states without hesitation that the present state of affairs in Constantinople is an outrage on humanity and a serious menace to the health of the world. Effective quarantine is impossible, owing to the magnitude of the problem.

Dr. Post then goes on to describe the indescribably filthy habits of the unspeakable Turk and the disgustingly dirty condition of the refugees who are being decimated by such diseases as typhus and dysentery and who, when the dry season comes, every camp and its surrounding heaps of filth will be active foci of contagion, and cholera and dysentery will claim its victims. With the present death rate the number of refugees will be reduced by one half within a few months. Moreover, if the Turks put into effect the new customs regulations their prohibitive duties on flour, milk and other necessities of life will end all relief work. All the American Relief and the British Sanitary Commission have been able to do thus far has been to feed and vaccinate the refugees, furnish them with mats and blankets, and also with baths, as far as facilities can be provided. According to Dr. Post's estimate the refugees now at Constantinople number about thirty thousand, and the majority arrived in the most wretched condition. They were forced to choose between deportation far into the interior of Asia Minor, among hostile tribes, or exile. Many died before reaching the sea and still more in the crowded, filthy ships. When they finally landed in Constantinople they could have been saved, the majority at any rate, by comfortable quarters and good food, but they were jammed into buildings pitifully inadequate and unsuitable and received no food save relief rations of a limited amount of bread and a daily dole of soup. In addition to bad conditions on land, there are many ships in the harbor crowded with refugees. There Dr. Post saw patients suffering from smallpox, typhoid, dysentery, pneumonia and typhus lying in huddled heaps together and he asks what is the remedy for the situation? In his opinion the only solution would seem to be the establishment in Greece of a vast refugee camp similar to that used by the British near Bagdad for fifty thousand refugees in 1918. No further deportations from the Black Sea should be tolerated, and something more than stereotyped official assurances should be insisted on by the allied powers. At present the Turkish Government is doing nothing for the refugees except to supply housing space, which is totally insufficient and inadequate. They have given no food, medicines, clothing, or fuel. With the Angora Government in its present frame of mind it is useless to await any friendly interest on behalf of the refugees. Greece is already greatly overburdened, the Constantinople relief committees are overwhelmed and the hospitals are overcrowded. The problem demands immediate drastic action by outside agencies, for the present situation is an increasing disgrace to all civilization.

Both Sir Patrick Hehiv and Dr. Post are agreed as to the refugee situation being at one and the same time a disgrace to civilization and a menace to the world. Dr. Copeland, of New York, a few months ago sounded a note of warning in this direction. The Turks are fatalists, as well as being of incurably filthy habits, but the refugee menace certainly seems to be a situation in which the Turks should be compelled to employ humanity and ordinary decency and cleanliness in order that these filth diseases should not overrun Western Europe and invade all the countries of the civilized world. The Allies might act through the League of Nations. Turkey joined the League when she thought it would be to her interests to do so, but flouted its authority when it did not fit in with her plans. The world is so upside down at the present time that it is difficult indeed to know where one country or another stands. No one would think now that Turkey was a beaten country, but rather one which could dictate terms. Still surely Turkey will not be allowed to be a standing menace to the health of the world.

DRUG ADDICTION AND DRUG TRAFFIC.

As was mentioned in a previous letter, drug taking, especially cocaine, has been greatly on the increase in this country since the war. In order to cope with the prevalence of this vice, an extremely drastic amendment is added to Dangerous Drugs and Pharmacy Act. Dr. W. G. Dixon of Cambridge, our foremost pharmacologist, has written to the *London Times* protesting against this amendment, which it is feared will curtail the doctor's right and privileges and not be effective. Dr. Dixon points out that in 1910 it was estimated that the consumption of morphine per head per annum in Austria was about one half grain; in Germany two grains; France, three grains; and the United States, thirty-six grains. Evidence of this nature led the United States, in December, 1914, to adopt what has come to be known as the Harrison Narcotic Law, which had the support both of the public and of the medical profession. In effect, this law dictates the manner of practising medicine and involves many irksome details and much clerical work for the doctor. It necessitates an army of officials—Federal, State, county and city—and every grain of narcotic must be traceable. Dr. Dixon proceeds to say that this law has now been actively enforced for seven years, and it is the universal opinion of those best able to judge that it has signally failed in its purpose. According to the estimates of Dr. Dixon, or rather those which have been given to him, the number of addicts and the amount of narcotics consumed are as great as or greater than in 1915. The Committee of the United States Treasury in 1921 figure that the country contained at least, one million addicts.

Dr. Dixon believes that the main reason for this is to be found in the fact that the law takes no account of the causes of addiction: the drug victim is regarded as a criminal, just as the insane were in medieval times. He states as if from intimate knowledge, that everything can be obtained if the price is commensurate with the risk, with the result that smuggling is rampant from end to end of America. Distribution is organized through underground channels, through underground dope peddlars. In other words he points out that the law has not diminished the supply, but only the distribution of the supply. The writer believes that it is the considered opinion of medical experts that the drug addict is a psychopath before ever he becomes addicted: that the ordinary normal man is as unlikely with every facility at hand, to become an addict of morphine or cocaine as he is to become a drunkard. These people take to narcotics just as they do to most other things which are foolish and wrong: addiction is a symptom of disordered mind, and simple custodial care with the withdrawal of the drug is no cure.

The British law, somewhat less drastic than the American law, came into force in September, 1921, and it is too early yet to see its effect. But Dr. Dixon pertinently says that we do not seem to have learned anything from the experience of our American brethren, since, in the amending bill to the Dangerous Drugs' Act now in the committee stage of the House of Commons, the medical profession is subjected to a number of pinpricks. He inquires whether our legislators cannot understand that the only hope of stamping out drug addiction is through the doctors, that legislation above the doctors' heads is likely to prove our undoing, and that addiction can be no more stamped out by prohibition than insanity can be stamped out. Yet in the amending bill practitioners not in actual practice are, in effect, forbidden to purchase narcotic drugs. Every practitioner is in practice, but in this case the "actual" is likely to be interpreted as "for gain." Registration under the Medical Act has up to now given certain rights; but registered doctors are now to be divided into two groups, and from one of these rights are to be taken away. The doctor is no longer allowed to prescribe for himself, and is to be subjected to horrible penalties for any infringements. In short, Dr. Dixon holds the view strongly that there can be little doubt that the passage of the amending bill, as it stands, will do positive harm. It will cause intense resentment in the medical profession.

It may be remarked that the medical man here is having his privileges, and many of his rights, curtailed. The introduction of insurance practice, known as panel practice, has had, to some extent, that effect, that is, he is liable, if he is a panel practitioner, and the majority of general practitioners take insurance practice, he is more or less under the thumb of the approved societies and seems likely to be more under their domination. The approved societies think no doubt that if they pay the piper they ought to choose the tune. The fact is that here medical men like the farmers and agriculturists generally have no power politically and they must endure whatever treatment those who hold the political power wish to mete out to them.

COCAINE AND ITS SUBSTITUTE.

Cocaine is the drug chiefly in favor here and, therefore, it is good news that a substitute for this drug in dental and eye work and minor surgery is reported to have been discovered in Chicago. This substitute has been mentioned favorably by Dr. C. W. Saleeby who has been traveling recently in America and Canada and is especially enthusiastic concerning it because then cocaine can be eliminated as a drug and will not have to be imported to this country for local anesthetic purposes. Dr. W. M. Beaumont wrote highly of this substitute a few weeks ago in the *British Medical Journal* and it is also stated that it has proved equally valuable in the hands of dentists. It is emphasized that this product has no attraction for the drug taker, it is not a derivative of cocaine and thus can be prescribed without restriction.

PANEL PRACTICE.

As hinted in a previous part of this letter, insurance practice has a considerable number of drawbacks from the point of view of both the practitioner and the patient. As said before, the Approved Societies have been called upon to make further contributions from their funds towards the cost of medical treatment and later on will be asked for still further contributions and they desire to have a voice and a voice that will be heeded, in the manner in which panel doctors conduct their practices. At the present time the medical profession will not meet the approved societies to discuss future terms but prefer to deal direct with the Minister of Health. The Minister of Health has given an indication to the approved societies that he will not conclude any arrangement without first consulting them. It seems, therefore, that the most fitting procedure would be to call for a conference, which should be attended by officers of the Health Department, representatives of the insurance practitioners and of the approved societies. There are complaints on both sides, which might be best settled by free and open discussion. As for the important question of treatment of the wives and families of insured persons, this must remain in abeyance on financial grounds. This question, indeed, especially that part of it which includes provision of surgical operations and matters of the kind, is largely bound up with the hospital question, and the hospitals to a great extent are solving this problem on their own account. It must be taken into consideration that a large number of British citizens at the present time are making contributions to the hospitals and very many of them are becoming paying patients. But, and this is a most important point, the exact position of the hospital in the medical service and the national insurance scheme has yet to be determined.

Book Reviews

HEART DISEASE.

Diseases of the Heart. By John Cowan, D.SC., M.D., F.R.F.P.S. and W. T. Ritchie, O.B.E., M.D., F.R.C.P. E., F.R.S.E. Second Edition. London: Edward Arnold & Co., 1922.

Although described as a second edition, this is virtually a new book. Many of the chapters are entirely new, while the remainder have been revised extensively. The opening chapters deal adequately with the recent anatomical and physiological work and with the pathology of the myocardium. There follow chapters on the examination of the heart; the irregularities; acute endocarditis; chronic valvular and myocardial disease; angina pectoris, disordered action of the heart, "D. A. H."; pericarditis; congenital disease of the heart; the diseases of the arteries and aneurysm of the aorta. There is a short chapter on the ocular manifestations of arterial disease, contributed by A. J. Ballantyne. The illustrations, for the most part original, are numerous and well selected.

The chapter headings are not always fortunately chosen. Thus, chapter IV, entitled The Examination of the Heart, considers only the polygraphic and electrocardiographic methods. The methods of physical examination are not stressed and very little attention is given to röntgen ray interpretations. Since the book is adapted particularly for practitioners and students, this is unfortunate. In a number of chapters certain important matters are omitted or given too brief attention. Thus, in the chapter on angina pectoris, no mention is made of the clear cut clinical picture in patients with sudden closure of a coronary artery. In the discussion of acute endocarditis, the subacute bacterial form is dismissed with a few sketchy remarks.

As a general presentation of the subject of cardiovascular diseases the book serves its purpose very well; it is complete but not comprehensive. A more detailed bibliography would greatly add to its value. More attention might perhaps have been paid to the historical aspects of the subject. The book is not a comprehensive treatise on cardiovascular diseases. It may, however, be recommended as an accurate and fairly detailed account of the important diseases of the heart.

SOCIAL ASPECTS OF SYPHILIS

Syphilis of the Innocent. A study of the Social Effects of Syphilis on the Family and the Community, with 152 Illustrative Cases. Made under a grant from the U. S. Interdepartmental Social Hygiene Board, by Harry C. Solomon, B.S., M.D., and Maida Herman Solomon, A.B., B.S. Washington, D. C.: U. S. Interdepartmental Social Hygiene Board, 1922.

The authors have made the praiseworthy and highly important attempt to present the subject of syphilis in its social aspects, portraying the practical problems as they actually arise in the handling of syphilitic cases and illustrating the text freely with cases from the clinic. In this attempt it would appear they have succeeded most admirably. They have produced a volume of exceptional interest, not only to the physician, but to the lay social worker and student, who comes in contact with the byproducts of syphilis in the form of mental and physical deterioration and inferiority. Exception should be taken to the unusual and altogether unnecessary use of patients' names in connection with the report of their cases. We cannot see that anything can be gained by using such distinctive names as Etta Prince, Howard Lincoln, Sarkis Sculos or Bertram Wood, in connection with their disease. It seems to the reviewer that the authors have violated the professional privilege, which should be respected inviolably as regards the clinical patient and the private patient alike.

The authors' conception of syphilis is up to date, clearly stated and manifestly based on a large clinical and sociological experience. They are to be congratulated on the result of their efforts.

SYMPTOMS

Klinische Symptomatologie innerer Krankheiten. Von Hofrat Prof. Dr. Norbe Ortner. Vorstand d. II med. Klinik der Univeresität Wien. Erster Band. Zweite Teil. Körperschmerzen (mit Ausnahme der Bauschschmergen). Second Edition. Price 240 marks. Berlin and Vienne: Urban & Schwarzenberg, 1922.

The first edition of this volume appeared in 1919 and has already been translated into English. According to the preface there was but little to add to the first edition. The various localities subject to pains considered in the book are cardiac region, loins, coccygeal region, shoulders, back, chest, extremities, musculature in general, bones, joints ,and head. A great drawback in a book on painful affections and pain is the total absence of illustrations.

PSYCHOANALYSIS WITHOUT SEX

Conflict and Dream. By W. H. R. Rivers. New York: Harcourt, Brace & Howe, 1923.

At last we have it. Psychoanalysis sans sex. Psychoanalysis with sails trimmed so as to appeal to any homosexual who wishes to believe that homosexuality is not sexuality, that homosexuality really is nothing but a myth. He gives dreams and shows, to his own satisfaction at least, that there is nothing sexual in them. Any tyro in dream interpretation would not be satisfied with the obvious avoidance of the fundamental material which is clearly apparent. The whole thing is clearly an attempted avoidance of fact and truth. No doubt personal affective states were responsible. All this could be forgiven but when an attempt is made to align himself with Freud and patronizingly link himself with him—this seems a bit thick. Even this, however, could be overlooked. The one thing that strikes the reader as pompous, arrogant, in bad taste and crude to the degree of causing an actual feeling of disgust is the banal attitude shown by T. Elliott Smith in his introduction. He takes it upon himself to interpret Rivers according to his own fantastic lights and on top of this states that Rivers really did not mean what he said about myths and other subjects. The text as written by Rivers is bad enough but with Elliott Smith's ludicrous annotations it becomes impossible.

DISEASES OF WOMEN

Die Pathologisch-anatomischen Grundlagen der Frauenkrankheiten. 24 Fortbildungsvorträge aus dem Gesamtgebiet der Gynäkologie. Von Prof. Dr. Wilhelm Lahm. Dresden und Leipzig: Verlag von Theodor Steinkopff, 1923. Pp. 301.

The twenty-four lectures given in a postgraduate course at the Staatliche Frauenklinik, Dresden, are reproduced in book form in response to a request for their publication. The author endeavors to make the abstract, lifeless, colorless and theoretical subject of pathological anatomy the fundamental basis of thorough clinical science and also the intermediary between the changes in the anatomical substrate and the visible vital phenomena; from there the way to symptomatology, exact and well founded diagnosis and the proper therapy is easy. The work is aided by valuable illustrations, models, etc., from the clinic.

The first chapter deals with the general pathological anatomy of inflammation, neoplasms and malformations. In the subsequent chapters, the five cardinal symptoms of fluor, hemorrhages, pain, amenorrhea, dysmenorrhea, and pressure symptoms (as evidenced by abdominal distention and difficult urination and defecation) form the framework upon which the structure of gynecological study is built up. A number of tables are added to aid the memory. The physician is advised to consider disease from the pathological anatomical viewpoint in every case; this naturally leads to a clear diagnosis, an etiological and rational therapy and correct prognosis.

This little book ought to be in the hands of every German reading physician interested in gynecology. It is a departure from the usual type of textbook on gynecology in that it treats the subject in an entirely rational manner and not in the usual humdrum sequence of etiology, pathology, diagnosis, prognosis and treatment.

VITAL STATISTICS

Vital Statistics; An Introduction to the Science of Demography. By George Chandler Whipple. Second Edition. New York: John Wiley & Sons, 1923. Pp. 579.

The book was planned by the author as a textbook for the study of demography, or the science of vital statistics. It was written especially for students who are preparing themselves to be public health officials, and for public health officials who wish a more detailed and recent exposition of statistical forms and methods. The book explains what statistics are, and what they are not; it teaches how to express vital facts through figures, their tabulation and their diagrammatic display; how to compute birth and death rates, and how to analyze the latter; how to adjust and standardize death rates, and how to make life tables; it shows how we may use vital statistics with "truth, imagination and power." The general arrangement of the book is rather an informal one, and the illustrations have not been gathered according to any specified system, but the principles of the statistical method are set forth in a clear, simple, and orderly manner.

In this second edition, the material has been revised on the basis of the census tables of 1920, which had not been published when the first edition was issued. There is also a new chapter on the estimation of future population of cities, including diagrams showing population growth in various parts of the United States. The international list of the causes of death has been revised in accordance with changes made by the Congress of Paris in 1920. There are several appendices: 1, References; 2, Model State Law for Morbidity Reports; 3, Law for the Registration of Births and Deaths; and, 4, Tables of Logarithms of Numbers.

DYNAMIC PSYCHOLOGY

Problems in Dynamic Psychology. By John T. MacCurdy, M.D. New York: Macmillan Company, 1922.

MacCurdy's book resembles the old adage of the temperamental month of March about coming in like a lion and going out like a lamb. He begins with a critic of psychoanalysis in which he promises many things and where one feels he is going to destroy some of the props of Freud's theory. He really supports these socalled untenable positions by his own reasonings. On the whole he deals more severely, perhaps unwittingly, with some of the narrower critics of psychoanalysis, such as Rivers, than with the fundamental Freudians.

However this may be, his final formulations are interesting in the extreme and show painstaking labor. Opponents of psychoanalysis will welcome the book, until they have carefully read it. Orthodox psychoanalysts will find it not to their liking until they have finished it. The book promises more than it gives and gives more than it promises.

STUDENT'S HANDBOOK OF SURGERY

Lehmanns medizinische Handatlanten. Band XXXIX. Grundriss und Atlas der allgemeinen Chirurgie. Von Professor Dr. Georg Marwedel. Zweite vermehrte und verbeserte Auflage. Mit 32 farbigigen und 201 schwarzen Abbildungen. München: J. F. Lehmanns Verlag, 1923. Pp. viii-454.

The author has attempted to steer a middle course between the elaborate textbook on surgery and the ordinary compend, so as to make it a handbook for the student who is just beginning to observe patients in the surgical ward or on the operating table. For the physician already in practice it is intended to serve as an aid in rapidly acquiring the newer teachings and advances in surgery, especially in the field of surgical bacteriology. The arrangement of the work is that which the author followed in his lectures as dozent at the Heidelberg University. The illustrations are numerous—both colored and in black—and were taken from actual cases at the Heidelberg Surgical Clinic; some of them were also taken from various well known atlases published previously. In this second edition the work has been thoroughly revised and it also includes many new chapters, such as those on wound dressings, cauterization and chemicals, wound diphtheria, blastotrichoses and sporotrichoses, echinococcus and cysticercus, diseases of wounds caused by animal toxins, and particularly, gas bacillus edema. The final chapter includes important surgical diseases of various tissues, which cannot be accurately classified. The striking illustrations of gas bacillus edema, which were taken directly at the front during the World War, deserve special mention.

HISTOLOGICAL TECHNIC

Handbuch der biologischen Arbeitsmethoden. Unter Mitarbeit von über 400 bedeutenden Fachmännern herausgegeben von Geh. Med.-Rat Prof. Dr. Emil Abderhalden. Abt. VIII, Methoden der experimentell morphologischen Pathologie, Heft 1. Allgemeine Methoden. G. Herxheimer-Wiesbaden: Histologische Technik. Berlin and Wien: Urban & Schwarzenberg, 1921. Pp. 336.

This is an intensely practical reference book dealing with the minutest details of every branch of histological technic. It constitutes Part VIII of a large series of handbooks on biological technical methods and the general methods of experimental morphological pathology. It includes a description of general microscopic technic, a description of the various instruments required, the examination and preparation of microscopical specimens, a description of the methods of fixation and hardening of histologic specimens, decalcification, the methods of freezing specimens and the methods of staining. The ingredients and the methods of preparing all stains are given. This book is most valuable to the laboratory technician and leaves little to be desired in regard to detail and completeness. It is a pity that an index has been omitted, as in a reference book such as this it is indispensable.

PHYSICAL DIAGNOSIS

Inspection, Palpation, Percussion, Auscultation. Leur pratique en Clinique Medicale. Third Edition. Par M. Maurice Letulle, Professor à la Faculté, Membre de l'Academie de Medecine. With 133 illustrations and 12 radiographic plates. Paris: Masson et Cie, 1922, pp. 337.

The book contains a graphic description of the various technical maneuvres which should form the fundamental training of every student of medicine. Each of the procedures of inspection, palpation, percussion and auscultation, as applied to the different regions of the body, are presented. The 133 illustrations of the book demonstrate the position of choice both of the patient and doctor in the examination, as well as the method of approach of the physician. The text, which precedes and accompanies every figure, gives concise suggestions in connection with each technical procedure. This is the third edition of the manual, which differs from the preceding ones by the addition of twelve good radiographic pictures with text emphasizing the importance of this adjunct to physical diagnosis. The volume should be of real value to medical students.

SYPHILIS OF THE NERVOUS SYSTEM

Die Syphilis des Zentralnervensystems. Ihre Ursachen und Behandlung. By Dr. Wilhelm Gennerich, Kiel. Zweite durchgesehene und ergänzte Auflage. Mit 7 Abbildungen. Berlin: Julius Springer, 1922. Pp. vii-295.

Gennerich gives a very complete survey of syphilis of the nervous system in all its manifestations He has discussed with great clearness the important intervening stage between primary syphilis and its development in the central nervous system, namely, the meningeal infection, the meningoencephalitis serosa infectiosa, through which alone the later developments come about. He urges carefully considered use of the means which the advance of knowledge puts into the clinician's hands. There is danger that specific treatment of early syphilis will so interfere with the natural allergy of the body that conditions are only made more favorable for the spread into the meninges and through them of the infection. The future fate of the central nervous system in regard to syphilis lies, therefore, largely in the physician's hands. One may not be in strict agreement with the writer in his theory or technic, yet his full presentation of the subject and the possibilities for good or for all of specific treatment, is invaluable for that advance of knowledge and thoughtful use of technical means for which he pleads.

MILITARY MEDICINE

Notes On The History of Military Medicine. By Lieut. Col. Fielding H. Garrison, Medical Corps, U. S. A. Reprinted from *The Military Surgeon,* Washington, Association of Military Surgeons, 1922.

An interesting outline of the history of military medicine has been furnished by Lieutenant Colonel Garrison, who was well fitted to profit by the opportunities afforded him to study military history when he was placed in command of the division of the medical and surgical history of the war in the surgeon general's office during the World War.

Colonel Garrison is well known to the student of medical history through his admirable volume *The History of Medicine* and his broad knowledge of the subject has enabled him to present within the two hundred pages of the *Notes on the History of Military Medicine,* an excellent conspectus of the principal points under this topic from the times of ancient Greek to and including the World War. The reader will, however, be possibly a little disappointed that so small a proportion of the volume, about sixteen pages, is devoted to the World War, for the author undoubtedly is in position to give us a comprehensive and informing volume on this latter subject.

CLIPPED WINGS

Quest. By Helen R. Hull. New York: Macmillan Company, 1923.

Gates of Life. By Edwin Björkman. New York: Alfred A. Knopf, 1923.

Reminiscences of childhood are coming to the fore. With Björkman's *Soul of a Child,* the peak was reached as far as the psychology of the adolescent boy is concerned. A girl is submitted to somewhat the same searchings in *Quest.* If anyone can doubt the criminal wrong done children in bringing them up under conditions of disharmony, strife, and petty bickering, this book should open his eyes. Like little Jean in the story it starts out to be a great book. One can see the child mind being whittled away, warped, contaminated, and thus the book progresses until it peters out tediously with Jean still seeking what she will never find without a thorough psychoanalysis—the self of which there was so much promise, now huddled into every day mediocrity.

The same fate has met Björkman's continuation of the *Soul of a Child.* Only in this case the family conditions were more morbid and the outcome more clearly inevitable from the start. The youth realizes the swaddling link with the mother, the mother country; he, finally, after many struggles to continue his home existence and yet steal some independence, makes the decisive break and is about to set out for America. Probably a further volume will set him on his feet, and reveal the man in him at last.

It is interesting to note how many Scandinavian writers have undergone the same weaning process, and only in flight have achieved their potentialities. The picture of Swedish growth and development, of the baffled stirrings of modernism and the fierce youth of the country with its bitter protest against mediocrity, convention, muddleheadedness, against the very country that had raised them to no greater heights than these commonplaces they decry, gives the book its real value. As far as Keith Wellander's young manhood is concerned, he becomes at best only a sympathetic mouthpiece of the universal experience.

INFLUENCE OF THE FRENCH MASTERS

Degeneration in the Great French Masters. By Jean Carrère. New York: Brentano's, 1922.

The method of attack used by Carrère is a valuable one. His psychology is good but some doubt is cast on his deductions by the questionable choice of material with which he has attempted to prove his generalizations. He attempts to show that the introversion of certain French authors is a recessive or regressive trait which he labels as degeneration. He postulates that the value of writing is not in the beauty of expression but in its relationship to adult constructive tendencies. So far so good. The only unfortunate thing about his thesis is his own inability to judge. He is apparently blinded by his own affects, the very thing he holds against the men whom he criticizes. There are two possibilities: first, that he is unable to see beyond the text, as one would judge from his attitude toward Zola and Stendhal, and, second, that he cares little about the distinction between phantasy and reality. He also overestimates the influence of the various writers he reviews. It would be well if he would give heed to some of the works on the psychology of the herd as outlined by Le Bon, Trotter and Freud in some of his recent works. Then he could see the relationship of identification, rationalization and expression of personal opinions.

◆

Medicoliterary Notes.

Medical supplies are so scarce in many parts of Russia that in one town the price of six capsules of quinine is one dollar and fifty cents in gold, and a single antiseptic tablet costs twenty cents.

* * *

Thomas Hunt Morgan, professor of experimental zoology at Columbia University, has recently published a monograph entitled Some Possible Bearings of Genetics on Pathology. Professor Morgan warns the experimenter against the danger, in his enthusiasm for applying the Mendelian laws, of premature conclusions drawn from insufficient evidence.

* * *

Dr. Frankwood E. Williams, Director of the National Committee for Mental Hygiene, has an article in the *Modern Hospital* for February on Mental Hygiene in 1922.

* * *

The Bursum Bill, affecting the ownership of land and the deciding of civil disputes by the Pueblo Indians, has aroused much interest in the Red man throughout the country, as is shown by the fact that a large number of leading periodicals have recently had articles, either on the problem of the bill itself, or about the Pueblos. Among these are the Dance Rituals of the Pueblo Indians, by Alice C. Henderson, in the April *Theatre Arts Magazine,* and What Is to Become of the Pueblo Indian? by Alida Sims Malkus, in *McClure's* for April.

* * *

A recent amusing and cleverly satirical publication is the *Rise and Fall of Prohibition,* by Charles Hanson Towne. The illustrations are by Peter Newell. Macmillan is the publisher.

* * *

Several of the large Parisian department stores, among them the Galèries Lafayette and the Louvre, have well equipped, successfully operated day nurseries for the babies of employees. Their purpose is to demonstrate that work for married women is not incompatible with motherhood. Each mother receives at the time of her confinement two months' leave of absence with full salary, and returns to work, bringing her baby with her. These mothers may arrive a half hour later, and leave a half hour earlier than other employees. The only condition of admission to the nursery is that the mothers nurse their babies. In order to do this, the mothers are permitted to leave their work every three hours.

* * *

Prof. M. V. O'Shea, of the department of education of the University of Wisconsin, is the author of a recently published volume on *Tobacco and Mental Efficiency.* The discussion of the subject is unprejudiced, and based on personal testimony, laboratory experiments, and psychological tests.

* * *

A comprehensive study of the Epidemiology of Botulism has recently been issued as *Public Health Bulletin No. 127* of the United States Public Health Service. The authors are Dr. J. C. Geiger, Dr. E. C. Dickson, and Dr. K. F. Meyer.

* * *

Human Life, How It May Be Prolonged to 120 Years, is the title of a book recently issued by Knopf. The author is Col. F. F. McCabe, of the British Army Medical Corps, whose great success in establishing and carrying out health and efficiency methods for the men in his charge during the war are well known to medical men in this country.

* * *

The *Report of the British Medical Research Council* for the year 1921-1922 discusses the work of the National Institute for Medical Research; experimental medicine and the research work of clinical units; industrial medicine and industrial fatigue; and research in specific subjects, among them, child problems, mental disorders, epidemiology, radiology and radiotherapy, and various specific diseases of significance in public health problems.

* * *

James Bissett Pratt, in his article, Religion and the Younger Generation, in the *Yale Review* for April, makes a plea for acceptance of the modern attitude toward religion as a step toward the working out of a faith that can be supported and substantiated by science. "That Christendom will ever return to the old creeds and to the old attitude to the letter of the Scripture is out of the question—our Fundamentalist friends may as well make up their minds to that once for all."

Practical Therapeutics

MEDICINAL TREATMENT OF HIGH BLOOD PRESSURE

By Charles Greene Cumston, M. D.,

Geneva, Switzerland.

To treat high blood pressure without treating the cause will clearly result in complete failure. In point of fact, it is rather singular to regard—as some do—arterial hypertension as a kind of morbid entity, when in reality it is a symptom of numerous very dissimilar pathological states, frequently having no relationship to one another. They are only related by the common fact that they end with temporary or permanent high blood pressure. Hence, it ensues —and this cannot be denied—that there is no treatment of arterial hypertension *per se,* but only treatment of those conditions giving rise to it.

For example, take a plethoric subject, a large eater and a heavy drinker; the plethora keeps up high blood pressure and all the usual hypotensive drugs will have no effect and are in reality contraindicated. This is an instance in which the frequent exhibition of laxatives and a reduction in the amount of food and drink will reduce the blood pressure.

King Louis XIV was in the habit of getting up in the night to eat a cold partridge and a pheasant, and during the day conducted himself royally at table as well. The august monarch would probably have died from the results of high blood pressure if his physicians—who were far more circumspect than the average physician of our day—had not ordered an average of five enemata in twenty-four hours, not counting the administration of laxatives. Quite unwittingly, the physicians of Molière's time often dealt with arterial hypertension much more efficaciously than do our enlightened practitioners at present.

However, we will not consider the methods in use for lowering the blood pressure in general and shall only consider those medicaments which have proved themselves to be vasodilators, viz., the nitrites, benzyl benzoate, and sodium citrate. Among the nitrites, trinitrin and sodium nitrite are most commonly employed, but it must not be forgotten that they may depress the heart. A keratin coated pill containing sodium nitrate, five centigrams, and extract of mistletoe, seven centigrams, is useful, three to be taken daily. The nitrite is liberated in the intestine.

Benzyl benzoate is given in doses of twenty drops in a five per cent. alcoholic solution nine times in twenty-four hours, but larger doses may be exhibited without any untoward effects. The hypotensive action of this drug is manifest. When injected into dogs a marked vasodilatation results in the domain of the splanchnic nerves, resulting in a lowering of the blood pressure. The drug may be given hypodermically in an oily solution containing from two to four drops in each cubic centimetre of olive oil.

Sodium citrate is prescribed in potion in doses of from three to ten grams in twenty-four hours. It must be exhibited for some time, and is more particularly indicated in plethoric subjects with hyperviscosity of the blood.

Tincture of garlic requires great precision in its use, because it should be prepared by a maceration of equal parts of hulled clove of garlic and water. The daily dose is from twenty to thirty drops taken at one dose and the drug should not be exhibited for more than two to four days at a time with an interval of five days. Prolonged exhibition results in arterial hypertension on account of the tonic effect on the heart.

But the best treatment of arterial hypertension is that which deals with the etiological factor. One of the most frequent causes is arterial atheroma and as we now know that arteriosclerosis and atheroma are unquestionably the result of cholesterin deposits in the bloodvessels, it follows that the only way to deal with this condition is to dissolve these deposits. This can be done with the alkaline phosphates, or, better still, with organic phosphatides, which dissolve the cholesterin. Their exhibition during two or three months generally lowers the blood pressure, and when this is once obtained the result is permanent, a result unattainable with the other hypotensive drugs, their action in this respect being only ephemeral.

NAUHEIM TREATMENT OF HEART DISEASE

By Louis Faugeres Bishop, M. D., Sc. D.,

New York,

Formerly Professor of Heart and Circulatory Diseases, Fordham University Medical College, N. Y. City; Physician to the Lincoln Hospital, N. Y. City.

The time has come when we are again in contact with people who have been to Bad Nauheim for a course of treatment, and any report from them as to conditions there has certain value. It has seemed to me that those who have remained long enough to take a satisfactory cure have been really benefitted. From a purely technical view of the matter, and omitting all political considerations, it must be acknowledged that no cure resort has replaced Bad Nauheim in its beneficial influence on cardiac disease. The reasons for this are not so easy to analyze as might be supposed; nevertheless, at the present time the Bad Nauheim treatment represents a concentration of experience in dealing with cardiopathic individuals that cannot be duplicated elsewhere in the world. There still remain a number of physicians whose experience dates from well before the war and who have resumed work, although, of course, some of the older ones are missing.

Nauheim methods must be considered as a whole, and I have even gone so far as to state on one occasion that even if the baths were omitted and the other elements of the cure were attended to, it would be a helpful place to send patients for a cure. I believe that in the Bad Nauheim surroundings the Nauheim bath has a definite usefulness and curative value, but the real cure is the result of a large collection of people, each having the same medical problem, who are congregated together under the care of a group of physicians. These men have had every chance to make every possible blunder in the management of heart disease, and who have profited by their experience.

One valuable fact they have learned is the absolute necessity of a general physical regeneration in persons with heart disease, as opposed to the fallacy of degeneration that results from the abuse of the almost universal rest cure. They have learned the importance of maintaining the hopeful attitude and the avoidance as far as possible of invalidism. They have learned that though the fatal outcome of cardiac disease is a fact, in many instances, nevertheless, it must be as little as possible brought to the notice of heart sufferers. How conditions are now at Bad Nauheim, I do not know, but in former years, under the strict Prussian government, no public funeral was allowed, and dissemination of the knowledge that a death had occurred at the cure was forbidden. The depressing effect on the guests of such a reminder of their peril was thus avoided.

The reason that the cure at Nauheim succeeds better than a spa treatment taken in America or elsewhere, is because the details are carried out in a different spirit, that is, a painstaking and laborious effort is made to impose a suitable regimen and its accessories in every minute particular. Americans in their own country do not take the time, or have the patience to submit to the instructions as to diet and exercise, which form such an important feature of the cure. They want to be cured in spite of themselves and expect the physician to remove the disease without any contributory effort on their own part. Another reason for failure is that these resorts in America are not popular as vacation resorts, and the frequenters of the spa go merely with the idea of getting through with a disagreeable task. This is entirely in opposition to the restful and leisurely atmosphere required if benefit is to be obtained.

The German word *Kur* carries an entirely different signification from our word cure. Our understanding of "cure" is that the disease is removed. In Germany, and in Europe in general, it may be said that "taking a cure" signifies that the patient, by means of rest, exercise, diet, and suitable treatment, is endeavoring to reconstruct his vitality and his energies, so that his disease, if not removed, is held at bay and his life and wellbeing prolonged. A very sensible European custom is to make a vacation by taking a cure, so that one returns to work and ordinary life greatly strengthened and benefitted in health. In this country a vacation often means a crowded rush, under conditions of hurry and discomfort that one would not tolerate in one's own home. The return from such a vacation often finds the patient in more need of rest than when he started.

Americans, especially those past middle life, could learn a valuable lesson from Europeans in this respect. They should give up a certain time every year in which to put themselves into the best possible condition. They should, during vacation, put in the "stitch in time" which will stand them in very good stead in their latter years.

If we examine the general method followed at Nauheim, we shall see some of the reasons why the *Kur* is so managed that it procures a reconstructive result. A patient who arrives at Nauheim is at once deprived of all customary drugs, and only allowed those which may later be deemed in harmony with the treatment. The question of rest is made one of the first essentials. The Nauheim air is one tending to produce drowsiness. Patients sleep better than usual there. Another factor which tends to produce this result is that the coffee used is always a kind from which caffeine has been abstracted, so that patients take their coffee without imbibing stimulant. Healthful sleep is not disturbed.

Another important essential is exercise: The little town is pleasantly laid out with shady walks and flower beds. The band plays in the afternoon, and patients can step easily out on the walks and are persuaded to take easy exercise almost without knowing it. Quite naturally they acquire the habit of spending most of the time in the open air. The fresh air life and mild exercise stimulate the nervous system and aid appetite.

In regard to the nourishment of the patient, a great point is made at Nauheim of nourishing and appetizing cooking. Meals are not heavy nor rich. The dishes are all freshly prepared; no madeover dishes are served. A practice is made of serving the meals deliberately, with waits between the courses, so that the feeling of bolting one's food in a hurry is done away with. There are plenty of dishes, consisting of light, plain food, in moderate portions, and as this is eaten slowly the appetite is satisfied, without a great quantity being consumed. In fine weather meals are served out of doors, and the band plays meanwhile, which all adds to the plan of making the meal a pleasant and restful proceeding, not the hurried effort to cram down enough food that it often is in our country.

One must not neglect to mention the upholding of a certain morale, which is indeed part of the essential spirit of the place. The whole regimen is so organized that patients are encouraged to feel they are going to get well. The psychology of optimism is induced to the utmost, as it is realized that the optimistic attitude is of extreme importance to the cardiac patient. For many of those who go to Nauheim, perhaps, the handwriting is on the wall, but in spirit of this all are encouraged in the hopeful outlook and when death intervenes, as it inevitably must, in some cases, publicity is avoided and the topic is kept from the other patients.

In spite of the fact that we believe all these details to be an important part of the sum total of good gained by the Nauheim cure, one cannot pass over the baths themselves as an unimportant feature. These provide the guests with a certain definite purpose, and apart from their therapeutic effect, make him think he is entering into a scheme for his own improvement and this has its psychological value. Even the matter of the baths, however, is not pushed too strenuously; the patient has certain rest days, when he does not take baths or any other treatment, thus gaining intervals of relaxation and the feeling of not being obliged to do anything.

The bath itself consists of a strong brine solution, with a considerable amount of calcium chloride, and a certain proportion of carbonic acid gas. The strength of the brine solution is an important point.

In taking the bath, the patient lies in the water for a certain number of minutes. The water is at first warm, but as the course progresses, the solution is made cooler and stronger. On account of the natural amount of salt and the carbonic gas saturation of the water, the patient is able to take the baths much cooler than he ordinarily would be able, and the effect on the heart is greatly enhanced.

A helpful type of exercise that is used in conjunction with the bath treatment is the resistance exercise. It has to be carried out with the help of an attendant, who gently resists the series of motions on the part of the patient, which are so designed as to include all the body muscles. In this way the tonicity of the muscles is improved and maintained.

It may be said here that there is nothing in the simple plan outlined as the essential Nauheim treatment which could not be achieved in America, with as good results. It is just because of its simplicity that the atmosphere of Nauheim is so difficult to reproduce in the artificial and overstrained conditions under which we exist. Good air, plain diet, rest, mild exercise, baths, are all obtainable, but the general management and psychological control of the patients by the physician or group of physicians are extremely hard to reproduce. In other words, the spirit of the Nauheim treatment has brought it to the point of a fine art. Results are gained by the reconstruction of the mental, physical and moral tone of the patient.

Some Aspects of Cardiac Disease.—John Hay (*British Medical Journal,* July 22, 1922) says that irregular heart action is not merely a matter of degree, that there are also several varieties, differing in type and in their significance. Auricular fibrillation is a sharply defined condition, recognizable without any special apparatus. The clinical picture may vary; usually the onset is sudden, the patient being conscious of the time of its onset, or it may develop insidiously; the ventricular action is completely irregular, but the rate may vary and often the rate of ventricular contraction is greater than the pulse rate; the rapid and relatively inefficient action of the ventricles increases the liability to cardiac failure and if the myocardium is unsound, or if there is marked arterial hypertension, the onset of cardiac failure is rapid and the distress is great (delirium cordis); dilatation of the heart is the result and not the cause of the rapid and disorderly action of the heart.

The etiology may be either, 1, rheumatic, commonest in mitral stenosis and during the age of twenty to fifty years, or, 2, senile, mostly in males and associated with myocardial degeneration, arteriosclerosis and chronic interstitial nephritis. Fibrillation may occur in any type of cardiac lesion, the fundamental change being the activity of the auricles —continued diastole and the presystolic contraction of the auricle disappears, as shown by the electrocardiograph and in the phlebogram. The auriculoventricular bundle loses its power of controlling the transmission of the impulses to the ventricle, and the ventricular action becomes disorderly.

The diagnosis is made by the history, the change in the character of the murmur and especially by the specific character of the arrhythmia, aided by the palpation of the pulse (haphazard beats); another diagnostic feature is the response to the digitalis group of drugs with a marked slowing of the ventricular rate and the appearance of coupled beats. It must be differentiated from sinus arrhythmia and heart block by the polygraphic and electrocardiograph records.

The therapeutic indication is to reduce the ventricular contractions to normal limits. In very urgent cases, 0.5 to 1.0 mg., strophanthine is given intravenously. In less urgent cases, full doses of tincture of digitalis, beginning with 1.0 or 1.5 drams (preceded by a purge) are given, or twenty minim doses may be given three or four times daily until the ventricular rate has reached 70 to 80; the digitalis should then be continued until sufficient digitalis is being taken to maintain this speed. The indications for stopping digitalis are: 1, a ventricular rate of 70 or lower; 2, nausea, vomiting, or diarrhea; and, 3, a coupled beat. If the tincture is not tolerated, Nativelle's digitalin granules or the tincture of strophanthus may be tried.

Auricular fibrillation can be terminated in fifty per cent. of the cases with quinidine sulphate, but the fibrillation often recurs and the administration of this drug is not without danger. When it is given, the auricular and ventricular contractions in the electrocardiogram should be carefully watched twice daily. Quinidine sulphate is given in capsules in ten doses of 0.2 gm. in twenty-four hours. It should not be given indiscriminately and the patient should be watched continuously.

Action of Quinidine in a Case of Complete Arrhythmia With Large Goitre.—E. Benhamon (*Paris médical,* March 10, 1923) reports the case of a woman aged forty-five in whom the menopause was soon followed by attacks of paroxysmal tachycardia of increasing frequency. They finally became practically continuous, with constant painful palpitation and dyspnea which precluded all bodily movement. The patient had had a small goitre for some time, but with the first attack of tachycardia it suddenly became much larger, and later was turgescent and pulsating. When first seen the patient had an extremely frequent and irregular heart action, with enlarged heart and liver râles at the bases of the lungs, edema, oliguria, and paroxysmal dyspnea. The pulsations in the goitre were as distressing to the patient as her heart action. Under digitalis diuresis occurred, the râles yielded, and dyspnea was reduced, but the arrhythmia and cardiac discomfort remained. Three tablets a day of 0.2 gram of quinidine sulphate were then prescribed, with the result that on the second day the pulse was reduced to 80 and definitely regular. The systolic and diastolic pressures were both reduced by 20 mm. of mercury. When the quinidine was interrupted for three days, two attacks of tachycardia recurred. A single attack took place after resumption of quinidine, and thereafter the patient remained in good condition and took up her former duties. Soon the quinidine was used only on alternate days or every third day, but when it was too greatly reduced the patient felt the need of a larger amount. Aside from the cardiac effect of the drug, the patient's goitre was not only reduced, but became smaller than it had been previous to the menopause.

Proceedings of Societies

AMERICAN THERAPEUTIC SOCIETY.

Twenty-third Annual Meeting Held in Washington, D. C., May 1 and 2, 1922.

Dr. Robert D. Rudolf, of Toronto, in the Chair.

(Concluded from Vol. CXVI, No. 11, p. 672.)

Quinidine Therapy in the Fibrillating Auricle.—Dr. L. F. Bishop, of New York, read this paper, which appears on page 528.

Circulatory System in Tuberculosis.—Dr. F. M. Pottenger, of Monrovia, Cal., read this paper, which appears on page 541 of this issue.

Myocardial Degenerations and Their Treatment.—Dr. A. E. Roussel, of Philadelphia, read this paper, which appears on page 555.

DISCUSSION.

Dr. H. C. Gardinier, of Troy, N. Y., in discussing these three papers, asked Dr. Pottenger how frequently he met the socalled small heart, dropped or ptosed heart, or bathycardia, in his clinical work; how frequently had he found tuberculosis clinically or at autopsy table associated with mitral valve disease, especially organic mitral stenosis.

In regard to Dr. Bishop's paper, he said he had had no experience whatever with quinidine, and that he had been so well satisfied with the treatment of auricular fibrillation by rest, quiet, diet, and digitalis that he had been reluctant to take up the use of this quinine salt, especially since serious results and some fatalities from its use had appeared in the literature.

Dr. Roussel, he thought, had not brought out in his paper the importance of a recognition of the gallop rhythm in the diagnosis and prognosis of myocardial disease. His experience had been that gallop rhythm occurred in most cases of severe myocardial disease, and while it might disappear it not infrequently returned and from the viewpoint of prognosis might be looked upon much as true pulsus alternans is considered.

Dr. Thomas F. Reilly, of New York, said that all conditions of heart disturbance were called myocarditis and the importance of valvular murmur was neglected. To say murmur meant nothing. The only proof that there was something wrong with the heart was the presence of a murmur, the only symptom which irregular hearts had in common. In every case of endocarditis, myocarditis was present, and every case of myocarditis could not be recognized as such with a murmur associated with one of the auricles. In treating these cases large doses of arsenic should not be used. When arsenic was used instead of mercury, one decigram injected into the buttocks he considered a "safe" dose. He also said that he knew of no single measure that did so much good in myocarditis as a dry diet. Concerning the use of quinidine, its administration for the first time would cause the pulse to run much higher. In about twenty-five or thirty per cent. of the patients taking quinidine, the fibrillation did not disappear.

Dr. C. G. Jennings, of Detroit, said that Dr. Pottenger had stated that tachycardia was not a symptom which occurred in tuberculosis more frequently than in other diseases. He thought this observation somewhat unusual, as he had found tachycardia to be a symptom in practically all early cases of tuberculosis he saw. Dr. Pottenger might see his patients at rest more frequently than the office consultant, and it might be that under these circumstances tachycardia was not so frequent. He believed there was usually a moderate tachycardia in early tuberculosis. He agreed with Dr. Roussel that morphine was a powerful stimulant in pneumonia, as it was in myocarditis. It was a respiratory depressant but not in moderate doses; only when given in large doses. Pneumonia patients needed rest and morphine often gave it when nothing else would.

Dr. J. I. Johnston, of Pittsburgh, said he wished to stress one thing which Dr. Roussel had already stated, and that was that much could be learned concerning the heart by checking up electrocardiographic work with fluoroscopic study. His experience with the use of quinidine had been limited, but all his work had been checked up by the electrocardiogram and he felt sure that quinidine did correct fibrillation in a certain number of cases. In one case particularly, the patient responded very well and had remained free from fibrillation for over a year. From a study of the literature, as well as from indirect personal knowledge, he believed the use of the drug was not free from danger, and that in all cases minimum doses should be used at first.

Dr. J. Diner, of New York, wished to take exception to a remark made by Dr. Jennings, as he did not think it would look well in the records to state that a physician had not time to give a careful examination of the patient. He believed the fluoroscope was a valuable means of diagnosis, but the expert diagnostician had perfected himself and did make accurate diagnoses without the aid of the fluoroscope.

Dr. Robert T. Morris, of New York, said he considered opium was better than morphine because of its slower and longer continued action, with fewer reactions. If one spoke in terms of the extreme action of the alkaloids of opium, it was possible to arrive at Dr. Reilly's view of the criminal phase of the subject. Opium, properly used, however, lessened the degree of destructive influence that was carried to the centres of consciousness when pain was engaged in sending these impulses.

Dr. R. D. Rudolf, of Toronto, wished to ask Dr. Pottenger if he had any record of cases where the auricular rate had been slowed by digitalis. He had not seen any. He had used quinidine a good deal in the Toronto General Hospital and in about fifty per cent. of the cases had been able to restore the auricular rhythm temporarily. This had been confirmed by the electrocardiograph. In several instances the normal rhythm had been sustained for two, three, or even four months. When the auricular fibrillation had recurred he had been able to remove it a second time by quinidine. He agreed with Dr. Pottenger that when the rhythm had been restored the patient was often not so much benefitted as one might expect. Quinidine was still in the experimental stage and its use should be confined to hospitals where the patients were under constant observation.

Dr. Hyman I. Goldstein, of Camden, N. J., said the terms myocardial disease and myocarditis had been used in the past to describe certain conditions of the heart muscle. Some preferred the use of the term myocardial disease; others, as in the present discussion, were using the term myocarditis. Which term was correct? Dr. Reilly had stated that every case of endocarditis was an indication of myocarditis. Was this always a true myocarditis, or was it myocardial disease or weakness.

Dr. John J. Johnston, of Pittsburgh, said he believed we could learn a great deal concerning the heart by electrocardiographic work with fluoroscopic study. He had had limited experience with quinidine, but all their work was checked up by the electrocardiograph. Quinidine did correct fibrillation in time. He had one case which responded very well, but he felt that the use of the drug was not free from danger. Small doses should be used at first in all cases.

Dr. Ross V. Patterson, of Philadelphia, said that the intermittent and recurrent character of fibrillation had not been emphasized. There could be no doubt that many cases of auricular fibrillation were recurrent and that there was a spontaneous tendency to crises in many cases, and that with the administration of quinidine it should be considered whether the restoration of mechanism was due to the use of quinidine or to the spontaneous tendency present in many of those cases. There could be no doubt that quinidine was protoplasmic. Possibly it was due to this fact that it had such an effect on the heart. No heart action was really increased with the use of quinidine. In some cases the heart was more affected with fibrillating auricles than it was with normal mechanism through the use of quinidine. It might be that despite its use the abnormal mechanism was converted to normal mechanism, with some danger, in the hope that the normal mechanism would remain after the treatment with quinidine was discontinued.

Dr. R. D. Rudolf asked Dr. Bishop whether he subscribed to the general statement that quinidine should not be used in a case of decided decompensation. He thought that should be known and borne in mind.

Dr. F. M. Pottenger, of Monrovia, Cal., said there were a few questions which had been asked him that he should like to answer. First, the small heart in tuberculosis was a difficult thing to determine and he thought the only way it could be determined was in the early cases. There had been cases in which hearts had been measured by the orthodiagraph. One man several years ago had a heart that measured small for him, which was the case in a large percentage of these cases of tuberculosis. All people have some tuberculosis. About fifty per cent. of adults have adhesions in the lungs. He could not explain the fact that people with small hearts should prove tuberculous. He saw no reason why. Certain conditions, however, might have a tendency to make the heart smaller. There was a possibility that the patient with tuberculosis did not fill his auricles as fully as normally he might, consequently there would be less blood in the auricle and he might have a smaller heart, but he did not believe it. It was simply a condition in which the heart was small. He said he meant that was the reason for it. Of course there was no average size for hearts because individuals varied and many of the statistics of that kind were not reliable. Dr. Jennings, he said, evidently did not understand his statement concerning the rapid heart. The rapid heart was a factor and was important simply when a patient was exercising and when a patient was at rest the heart was not necessarily rapid. The more these things were studied the more symptoms would be understood and the better they would be able to understand their patients.

Dr. A. E. Roussel, of Philadelphia, said that regarding the relative proportion of myocardial disease to valvular disease attended with symptoms meant coexisting myocardial disease. As long as the muscle in valvular disease remained healthy there were practically no symptoms and the individual was capable of normal effort. Tachycardia in tuberculosis was more the question of heart instability, increased frequency on slight exertion and perhaps diminished frequency at rest. Regarding the gallop rhythm, the various changes in rhythm in myocardial disease were all of them more or less significant and yet it was interesting to note that not infrequently in patients over forty years of age an intermittent pulse might develop and continue for the rest of the patient's lifetime without an appreciable shortening of it. He also mentioned tropical infections and these necessarily included valvular disease associated more or less with sluggish intestines, resulting in a condition of toxemia which seemed to be productive of cardiac change.

Regarding the differentiation between the tachycardia which occurred in tuberculosis and that which occurred in hyperthyroidism and the soldier's heart, or the syndrome heart, it was here that he must insist that the diminution of the basal metabolism was of prime importance in distinguishing these relative conditions. Concerning the use of morphine, he was glad that the speakers had agreed with him regarding its usefulness in acute dilatation of the heart, and incidentally he wished to make reference to Dr. Reilly's remarks on the use of morphine in pneumonia. He thought he was in error. Morphine was of prime importance in pneumonia, but it should be used with the greatest caution at or near the time of the crisis. Recently he had had a case in New York, a patient sixty-three years of age with a massive pneumonia on the left side and a bad myocardial frequency with acute nephritis. To the astonishment of all, the patient made an unexpected and perfectly good recovery. Regarding the use of quinidine, it was his experience, although limited to hospitals, that it should be exhibited practically only in hospital cases that could be kept carefully under observation, and it would seem, as the results desired could practically be secured by other methods and as there was distinct proof of certain untoward effects that might occur, that this exhibition should always be used with caution.

Dr. L. F. Bishop, of New York, said that quite a number of interesting questions had been raised. First, as to the question of digitalis. He did not think they would ever know all about it, but they were learning things all the time, and fibrillation of course had aided them more than anything else. When it was recalled that only since 1908 had they known anything about fibrillation, it was easily understood that all the natural history of it could not yet be known. He stressed that question of natural history because he thought that only from natural history could the treatment be judged. Take the very question of what would stop fibrillation; one of the few things that stopped fibrillation was digitalis. Take the question of the drugs that had a tremendous reputation. Thousands of doctors used them. He did not doubt that they were taken up in every college. Look at the cactus for instance. No doctor he had ever known had ever been able to discover any good in cactus, but it had a great reputation in heart disease. To say that fibrillation would be present in a regular heart was not true, for if a heart was regular it was not fibrillating. Digitalis never made a heart regular in the world. It made a great many irregular. It had nothing to do with making a heart regular. That was a great mistake in the profession. It never made a heart regular, but it did a great many other things. He thought that the consensus of opinion was that it was not safe to use quinidine in a decompensated heart.

Transfusion.—Dr. Edward H. Goodman, of Philadelphia, read a paper on this subject, which appeared in the February 21, 1923, issue of the Journal.

Dr. William Seaman Bainbridge, of New York, in discussing Dr. Goodman's paper, said that during the early years of the war he had seen a great deal of work being done, on the other side, and later, in 1920, when transfusion had been used in cases of chronic sepsis where the patients' condition seemed to remain stationary for weeks and months, with no gain and apparently little loss. These cases had been put on the upgrade by the use of transfusion.

Dr. W. W. Babcock, of Philadelphia, called attention to the fact that transfusion did not absolutely supply loss of blood. In transfusion the blood was not the same as loss of blood by hemorrhage or other cause. In certain cases, such as those of hemorrhage where the patients were apparently dying from loss of blood, transfusion seemed at times valueless. He recalled the case of a soldier who was dying from hemorrhage. He was placed on the operating table and was given a quantity of blood, a very large and rapid transfusion, and he died on the operating table. They could not replace the condition, could not restore him in the least. On the other hand some of the results that had been obtained from transfusion could have been obtained by use of a very simple solution. He thought they should be very thorough in determining results. In some cases they get good results and sometimes they did not.

The Standard Treatment of Malaria, Its Effectiveness in Relieving the Clinical Symptoms of Malaria.—Dr. C. C. Bass, of New Orleans, La., read a very interesting paper on this subject, in which he stated that the standard treatment for malaria recommended by the National Malaria Committee was, for the acute attack, ten grains of quinine sulphate by mouth three times a day for a period of at least three or four days, to be followed by ten grains every night before retiring for a period of eight weeks. For infected persons not having acute symptoms at the time, only the eight weeks' treatment would be required. Dr. Bass discussed the effectiveness of the first part of the treatment for the purpose of relieving the clinical symptoms. The paper will be published in full in a later issue.

Dr. S. L. Dawes, of New York, who opened the discussion, said that most of them were not competent to discuss Dr. Bass's paper as they did not see malarial fever. He wished, however, to express his appreciation of the paper.

Dr. E. P. Fick, of Seattle, Wash., asked Dr. Bass if he had ever used quinine intravenously in treating malarial conditions.

Dr. Robert E. Rudolf, the chairman, said he wished to make a single statement. When he first began the practice of medicine in the northeast section of Philadelphia in connection with the Episcopal Hospital there, a large number of cases of malaria had been treated. While, as a rule, in acute cases quinine was liberally employed, and successfully, there was a class of cases in which it became necessary to use some other treatment. In these well defined cases they had employed cinchonidia sulphate, and had a feeling there was better effect than with quinine itself. He wished to know whether Dr. Bass had ever hit upon anything other than quinine that was specific in the treatment of malaria.

Dr. C. C. Bass, of New Orleans, in answer to the question as to whether previous quinine treatment might make an individual require a larger amount to relieve the clinical symptoms, said that some good authorities believed that it did, but he doubted it. He did not know of any scientific experiments that furnished the answer to this question. The intravenous administration of quinine had no place in the treatment of malaria except in very rare instances in which it could not be given by mouth; and only when it was believed that the patient's life was in great danger on account of the disease. He did not think any preparation other than cinchona could be more effective than quinine in relieving clinical symptoms, since it was practically one hundred per cent. effective.

Spinal Anesthesia in Relation to Associated Therapeutic Problems.—Dr. W. Wayne Babcock, of Philadelphia, read this paper, which will appear in a later issue.

There was no discussion.

Industrial Medicine a Community Problem.—This paper by Dr. Andrew McFarlane, of Albany, N. Y., was read by title. There was no discussion.

Some of the Activities of the Medical Corps of the United States Navy in the War and Postwar Periods.—Dr. William Seaman Bainbridge exhibited moving pictures showing some of the activities of the United States Navy in the physical reconstruction and physiotherapy in the reconstruction period after the war. He also gave a travelogue with the reels of some of the methods and practical results of lessons learned in the World War, from medical, surgical and sanitary viewpoints.

Abstracts from Current Literature

HEART AND BLOODVESSELS.

Arteriosclerosis and Arteriolosclerosis.—J. Pal (*Wiener klinische Wochenschrift,* July 27, 1922) states that in arteriosclerosis it is important to control carefully the fluid intake by the patient. In advanced cases, the fluid intake should be as low as possible, including the water content of the food. Alcoholic beverages should be restricted or prohibited as patients with arteriosclerosis are peculiarly susceptible to vascular poisons. Effervescing beverages (carbonic acid) and beer should also be avoided. The ingestion of excessive amounts of fluid may be counteracted by the administration of a diuretic once or twice a week. There is no foundation for the belief that theobromine and iodine have any curative effect on the disease process: they do not reduce the blood pressure. Diuretin dilates the bronchi and the coronary and renal arteries and indirectly, through the action on these arteries, it probably lowers the high blood pressure when no rigid anatomical changes have occurred. Iodine occasionally produces a considerable loss of weight, which also helps somewhat. Blood letting is an important therapeutic remedy in acute cases and cardiac insufficiency (pulmonary edema), but repeated venesections are useless and may even lead to hypertonia and secondary anemia. The treatment of attacks of stenocardia, cardiac asthma, and angiospastic conditions, is an important part of the therapy. Heat and vasodilator remedies are valuable. The treatment with aspirin is important, but narcotics (especially morphine) must be avoided: for this purpose, aspirin, 0.5 to 1.5 or 2.0 gm., given best per os or per rectum in a solution of sodium bicarbonate, has been found useful in conditions of vascular pain. In attacks of stenocardia, intravenous injections of papaverine are considered preferable to their subcutaneous injection; recently the intravenous injection of atropine or novatropine has been found very effective. Morphine, if used at all, should not be given alone; combinations of papaverine, or possibly pantopon, domopon, etc., are preferable to pure morphine. In angiospastic processes of arteriosclerotic origin, the use of quinine has recently been recommended and deserves a trial.

A Paraganglioma of Zuckerandl's Organ Associated with Hypertrophy of the Heart and Kidney.—Max Hausmann and Sophie Getzowa (*Schweizerische medizinische Wochenschrift,* September 14, 1922) report the following clinical and anatomical symptom complex in a patient who died of grippe pneumonia: a chromaffin tumor (paraganglioma) of Zuckerkandl's organ, hypertrophy of the heart and kidney, hypertension, polyuria and transient glycosuria. This apparently idiopathic cardiac hypertrophy, the authors attribute to the effect of the tumor or its adrenalin, and they designate it as cardiac abnormalities of the adrenalin heart. The myocardium showed changes, which have also been found in the hypertrophied hearts of rabbits following intravenous injections of adrenalin (isolated indurated foci, partial diffuse sclerosis and an extreme hypertrophy of the muscle fibres); there was no vascular sclerosis. The symptoms of cardiac hypertrophy and of hypertension clinically suggest chronic hypertensive renal diseases and hypertensive arterioscleroses with cardiac hypertrophy and the polyuria and glycosuria suggest diabetes insipidus and socalled innocuous diabetes. Therefore, a hyperadrenalinism or an adrenalin heart must be considered in hypertonic cardiac hypertrophies, which results from a tumor or a hypertrophy of the chromaffin tissue. The authors consider such a tumor as related to the endocrine adenomas, some of which are characterized by a capillary network with masses of cells in its coils. These include certain tumors of the hypophysis, the thyroid, the parathyroids, the chromaffin tissue and the cortex of the adrenals; also the socalled hypernephroma. The endocrine adenomas may have hormonal action.

The "Sixty-Six" Pulse.—Jesse G. M. Bullowa (*Medical Clinics of North America,* November, 1922) lays emphasis upon the importance of the sixty-six a minute pulse rate as an objective sign of pain. In acute conditions it is a physical sign of vagotonia—either of an overacting vagus or of a deficient sympathetic innervation of the heart. The sixty-six pulse as evidence of vagus tone is an important and often disregarded sign of the severity of irritative abdominal lesions, but the intestinal tract is not the sole source of such vagotonic slowing of the pulse rate, as it may also be produced by spasm of the ureter. It may also occur during the administration of digitalis before nausea or coupled beats appear (ample vagus stimulation) and in stimulation of the sympathetic system by diphtheria toxin in diphtheria.

Hemostatic Action of Pituitary Extract.—Perrin, Hanns, and Stefanovitch (*Paris médical,* March 10, 1923) tested the action of posterior pituitary extract on blood coagulation, blood pressure, and pulse rate in ten patients suffering from miscellaneous disorders, independently of actual hemorrhage. One to two mils of the preparation were injected intravenously. In eight cases the coagulation time was more or less markedly shortened, in one case unaffected, and in a case of purpura, lengthened. The effect on blood pressure was less constant. In four cases it was lowered by fifteen to twenty millimetres of mercury and in two by thirty to forty millimetres. The reduction of pressure began in ten minutes to one hour after the injection and persisted for two to five hours or longer. The extent of reduction did not parallel the dose injected. In the remaining four cases the blood pressure was unaffected. The pulse rate was unchanged in five cases; in three it was slightly lowered; in one it dropped from eighty to forty, and in one it was increased. The actions on the pulse rate and blood pressure seemed to be independent, as the case with greatest pressure reduction showed no change of rate and the one with greatest pulse lowering showed no reduction of pressure. The hemostatic action of pituitary extract appears to be mainly due to its action on blood coagulation.

The Failing Heart.—Paul D. White (*Boston Medical and Surgical Journal,* November 23, 1922) says with regard to the treatment of anginal failure: Rest is essential, mental and dietetic as well as physical. Nitroglycerine or amyl nitrite are, of course, invaluable and should always be carried by the patient suffering from heart pain of the anginal type. Morphine should be given freely if necessary; when much of it is necessary coronary thrombosis is probably the underlying condition. Digitalis is generally contraindicated in the anginal type of heart failure, but may help a good deal if the heart pain is due to right ventricular fatigue in mitral stenosis, or to the left ventricular fatigue in chronic hypertension. A light diet, particularly light in bulk, is of great importance; quantity is much more vital than quality. Five small meals a day, with the last one the lightest, forms a good program. Avoidance of taxing business cares as well as absolute omission of abruptness in physical activity, must be advised. Rest will not only cause the cessation often of anginal pains, but incidentally is by far the best treatment for hypertension which may or may not be associated with the angina. As low a blood pressure as 115 mm. systolic has been met with in marked coronary sclerosis. If syphilis is proved or likely antileutic treatment, begun with care, may be very beneficial.

Syphilis of the Heart and the Aorta.—Harold Wiltshire (*Clinical Journal,* September 27, 1922) says that the general treatment and management of heart failure due to syphilis are exactly the same as for heart failure due to any other cause. In the attack against the syphilis itself, however, it is well to remember that salvarsan injections are not free from danger when the heart and aorta are affected. An injection may be followed by an acute exacerbation of inflammation in any syphilitic focus, just as an injection of old tuberculin may provoke an intense reaction in a tuberculous lesion. If, as is so often the case, the coronary arteries happen to be involved in the syphilitic process, an injection may precipitate an anginal attack, or sudden death. (In the case of heart failure quoted above, the story suggests a general myocardial reaction following an injection.) In consequence it is wise, if salvarsan is given, to take precautions by administering a previous course of iodide and mercury, by keeping the patient in bed for the injection, and by starting with a small dose, for instance, 0.1 gm., and by increasing the dose gradually.

Cardiac Complications of Gonorrhea.—W. S. Thayer (*Bulletin of the Johns Hopkins Hospital,* October, 1922) analyzed the cardiac complications of gonorrhea occurring at the Johns Hopkins Hospital during thirty-three years. In 176 instances of acute endocarditis of determined origin, twenty, or 11.3 per cent. were gonococcal. But little evidence could be obtained as to the relation of the time of onset of the cardiac involvement to the appearance of the disease or other complications, arthritis occurring in only 41.1 per cent. of the Johns Hopkins cases, though in 68.5 per cent. of fifty-four cases collected from other sources. The cardiac complications of gonorrhea were usually acute or subacute vegetative and ulcerative endocarditis, appearing at varying periods during the course of the infection, with a sudden or more gradual onset, but usually rather acute, with chills and high remittent or intermittent fever, rapidly developing anemia and considerable leucocytosis, and frequently a petechial eruption. Embolic phenomena are common. The urine shows albumin, casts, often blood, and in the longer cases anasarca and hydrops are evidence of a grave nephritis. The course usually was from four to nine weeks. The aortic valves were those commonly involved, but as in all acute endocarditides, the right side was more often affected than in the chronic, socalled rheumatic valvular disease, and in the cases studied, involvement of the pulmonary orifice was rather common. The cardiac involvement was not restricted to the endocardium, as endoaortitis, pericarditis, and suppurative myocarditis are not unusual. Gonorrheal endocarditis is in general a malignant process having a progressive and fatal course, occupying a position in its virulence between the slower and more subacute Streptococcus viridans and Bacillus influenzæ infections and the more virulent Staphylococcus albus, Staphylococcus aureus, pneumococcus or Streptococcus hemolyticus endocarditides.

Mechanical Vibration Therapy.—M. L. H. A. Snow (*American Journal of Electrotherapy and Radiology,* April, 1922), in presenting the report of the committee on mechanical vibration therapy and apparatus, gives the following summary: 1. Mechanical vibratory treatment has a marked effect on blood pressure. 2. In some cases of hypotension it may raise blood pressure. 3. In cases of hypertension, it has an effect to lower blood pressure. 4. In cases of reversed postural relation of blood pressure in lying and sitting it corrects the abnormal relation or if the disparity is great it induces an approach to the normal. 5. The ordinary cases of reversed postural relation of the pulse rate are corrected by mechanical vibration. 6. Mechanical vibration lowers high pulse rates, as in cases of chorea or exophthalmic goitre, vibratory treatment being given in the intervertebral spaces from the second to the sixth dorsal vertebra for five minutes. 7. Mechanical vibratory treatment in cases of lack of functional tonicity of the heart muscle, without being diseased, is capable of increasing the tone of the heart either directly or reflexly by nerve stimulation. 8. Mechanical vibratory treatment induces contraction of dilated bloodvessels. These results might be duplicated by other forms of stimuli, but the relative values of such are as yet unknown.

Contribution to the Study of Essential Hypertonia.—W. Kerppola (*Finska Läkaresällskapets Handlingar,* July-August, 1922) calculates that in essential hypertonia the blood count shows an increased hemoglobin content in about fifty per cent. of the cases and increased red corpuscle content in about forty-five per cent. of the cases, slight leucocytosis in about thirty per cent., and a marked mononucleosis in about sixty per cent. In sixty per cent. the blood coagulation was normal, in forty per cent. somewhat reduced. The blood sugar content on a fasting stomach was usually normal. Reduced sugar tolerance was observed in eighty per cent. of the cases, of which about twenty-five per cent. showed alimentary glycosuria. Diabetes is quite frequently combined with hypertonia in persons over forty years of age, but only exceptionally in younger people.

Rapid Digitalis Effects by Oral Administration.—Francis R. Fraser (*Lancet,* September 30, 1922) finds that digitalis administered by the rapid method, with doses of one and a half drams, one dram and half a dram of the tincture at intervals of six hours, produced a definite and prompt slowing and clinical improvement in cases of auricular fibrillation with rapid ventricular rates in five to twelve hours; the maximum effect was noticeable in fifteen to thirty hours. This method of administration of digitalis is not suitable to cases of normal rhythm, but it is of great value in cases of auricular fibrillation with rapid ventricular rate and urgent symptoms.

The Process Which Results in Auricular Fibrillation.—James Mackenzie (*British Medical Journal,* July 15, 1922) asserts that the term auricular fibrillation is not descriptive, because the fibrillation is a result and not a cause of the loss of control of the heart muscle, and for it he proposes the term auricular paralysis. Just as in all other muscle tissue, fibrillation results only when the muscle is uncontrolled by its motor nerve. The change in the action of the heart muscle takes place in the sinoauricular node or in its connection with the auricle. The same result occurs when the ventricle escapes from the control of the conducting system.

Central Influence of Atropine and Hyoscine on the Heart Rate.—W. J. R. Heinekamp (*Journal of Laboratory and Clinical Medicine,* November, 1923) concludes from his experiments that atropine sulphate in small doses causes inhibition of the heart, which he believes is due to direct stimulation of the medulla. His experimental findings corroborate the results of McGuigan and Harris, both of whom obtained clinical evidence that atropine in small doses, 0.001 gm., produces slowing of the heart, while larger doses accelerate it. The action of hyoscine is similar to that of atropine on the turtle brain.

Relation of Hypertension to Cardiorenal Diseases.—Nellis B. Foster (*American Journal of the Medical Sciences,* December, 1922) can find no adequate evidence for belief that hypertension is a predominant factor in the causation of arteriosclerosis. Our present knowledge seems to indicate in a general way that organic change in the kidneys and vessels may arise in diverse manners, the least indefinite of these being through intoxications of infectious origin. There are suggestions that intoxications resulting from abnormal metabolism may have a similar effect. These intoxications produce at first only functional disorders chiefly referable to the nervous system; when persistent, they induce organic changes affecting the bloodvessels and kidneys.

Theory of Suprarenal Arterial Gangrene.—V. A. Oppel (*Lancet,* July 15, 1922) states that not infrequently a spasm of the arteries, causing a complete blanching of the fingers is seen, which is ascribed to a comparatively slight increase in the quantity of adrenalin circulating in the blood of such patients. As a result of his experiments, the author asserts that in human pathology, in suprarenal arterial gangrene, the concentrations of adrenalin must be less than one in one hundred million, as concentrations of about one in eighty million produce ischemic paralysis, which, if such concentrations are maintained for some time, must rapidly end in gangrene of all the limbs simultaneously. Clinically, no such occurrence is known. In human pathology, the hyperadrenalinemia only gradually disturbs the nutrition of the arterial walls with a resulting change in them and in the contained blood. The existence of such an hyperadrenalinemia is recognized by an increase in the vasoconstrictor effect of the blood serum occurring in socalled spontaneous gangrene. The author's contention is also substantiated by the result of treatment of the socalled spontaneous gangrene by excision of the left suprarenal gland, on the one hand, and by the pathological anatomical data on the other.

TUBERCULOSIS.

The Röntgenogram and the Therapeutic Indications in Tuberculosis of the Bones and Joints.—F. de Quervain (*Schweizerische medizinische Wochenschrift,* October 19, 1922) believes that although the roentgenogram is an important element in the more accurate diagnosis of tuberculosis of the bones and joints, nevertheless, it is only exceptionally of value as such in the determination of the therapeutic indications, inasmuch as other factors than the anatomical diagnosis of the local disease also come up for consideration in the selection of any treatment. Neither can the roentgenogram alone determine the nature of the treatment while a case is being followed roentgenographically during a course of treatment, as here again the other clinical symptoms of a local and general nature must also be considered. Not infrequently, a circumscribed local rise of temperature and local tenderness show that something is wrong at a particular site even though the roentgenogram shows nothing abnormal and no recent changes in the bone. On the other hand, the roentgenogram occasionally casts doubts upon the process of healing, even in those cases in which the clinical symptoms show that the process is no longer active. Taken all in all, it appears that the roentgenogram, *per se,* is just as unable to serve as a guide in the determination of indications of treatment as any other means of laboratory diagnosis. Roentgenography attains its full value as an indicator of treatment only in its associated use with the other medical and extramedical factors upon which the choice of any method of treatment depends in the individual case.

The Röntgenotherapy of Tuberculosis.—Hans E. Walther (*Schweizerische medizinische Wochenschrift,* October 19, 1922) maintains that it is advisable to use at first only small doses of x rays in every form of tuberculosis, such as about twenty to twenty-five per cent. of the skin unit dose and never more than forty per cent. It is also desirable to use a uniform, homogeneous irradiation, which renders the calculation of the surface dose easy. Roentgenotherapy should be tried in every form of tuberculosis, except those cases in which the general condition is much reduced (as in a positive amyloid reaction). It should also be omitted in all caseous and suppurative processes, in renal tuberculosis which cannot be drained externally, where it should be used only as a postoperative treatment, and in all those forms of pulmonary phthisis which show a pronounced tendency toward breaking down. Roentgenography is valuable only when it is used in rational combination with other tried methods of treatment, as in socalled surgical tuberculosis, in which the other necessary surgical measures must not be omitted. Caseous matter and pus must be allowed to drain and in involvement of the supporting skeleton thorough relief from weight bearing must be provided for. Immobilizing dressings must be avoided and in involvement of the spinal column and of the lower extremities, bed rest is absolutely necessary. Natural or artificial heliotherapy is a valuable aid. Hospitalization should be avoided wherever possible. If the general condition is poor, arsenic, preferably in the form of arsacetin, is indicated. Roentgenotherapy is undoubtedly valuable in tuberculosis.

Tuberculosis From the Clinical Point of View.—Basing his conclusions on the fundamental investigations of Rankes, Wilhelm Neumann (*Wiener klinische Wochenschrift,* October 19, 1922) classifies tuberculosis, from the clinical point of view, into three groups: 1, the primary complex, consisting of cases with a primary focus plus involvement of the draining lymphatics up to the regional lymph nodes; 2, the cases with the proliferating primary complex—the primary focus from which the dissemination of the tubercle bacilli reaches the blood—which may be either malignant (general miliary tuberculosis), virulent (hematogenous tuberculosis with a more favorable prognosis), or bland (tuberculosis of the eye, chronic recurrent pleurisy, chronic polyarthritis, etc.); and, 3, massive infiltration with an existing immunity as a result of a healed primary complex (the usual forms of chronic pulmonary phthisis). The various forms of tuberculosis may be fitted into this scheme.

Tuberculosis in Children.—This subject is dealt with from the viewpoints of the pediatrist, the orthopedist, the internist, and the surgeon, in the *Boston Medical and Surgical Journal,* September 28, 1922. John Lovett Morse is of the opinion that the preventive treatment is by far the most important. When tuberculosis has developed the treatment consists of rest, food, fresh air both day and night, and all the sunlight there is. He has no confidence in any drug treatment, except for the relief of symptoms. Tuberculin treatment seems to him to have done more harm than good. Joel E. Goldthwait says that in tuberculosis of the bones and joints the first thing is to prevent deformity, or correct deformity if it has occurred, the second to put the part in the position of physiological rest and then allow function in so far as the part will tolerate it. Anything the individual, not someone else, can do with a diseased part is little likely to do harm. As fast as the child is able to use the part, it should be encouraged to do so. Use stimulates circulation, encourages bone repair, and stimulates the cells about the diseased portion so that they will be stronger and able to control the disease, rather than to weaken those parts by too great inactivity. Henry D. Chadwick recites the points upon which a diagnosis of juvenile tuberculosis must be based as follows: 1. History of frequent colds or predisposing causes such as measles, whooping cough, and influenza. Also the frequent association of phlyctenular disease and scrofuloderma with hilum tuberculosis should be kept in mind. 2. Symptoms of tuberculin toxemia, viz., fatigue, malnutrition, anorexia, febrile attacks. 3. Exposure to tuberculosis in the home. 4. Positive cutaneous tuberculin test. 5. Evidence of enlarged tracheobronchial lymph nodes and infiltration or thickening of the adjacent tissues as demonstrated by physical signs and confirmed by röntgenogram. Lloyd T. Brown says that surgery, meaning probably operative surgery, is and should be the exception in these cases, and that it should be always only an incident in the general treatment, which is necessarily prolonged.

Erythema Nodosum and Tuberculosis.—A. Wallgren (*Acta Pædiatrica,* July, 1922) reports several illustrative cases and concludes that erythema nodosum is most probably a disease *sui generis,* a specific acute, infectious disease which usually appears sporadically, requiring a certain predisposition of the organism in order to develop. A previous tuberculous infection may provide such a predisposition. When several people coming in contact with each other have been infected with tuberculosis, and thus have been rendered predisposed to erythema nodosum, the disease may assume an epidemic character. The fact that erythema nodosum is so often followed by tuberculosis may be explained by the fact that this most frequently occurs in children who are suffering from latent tuberculous infection which is revived during the weakened condition caused by the erythema nodosum.

Radium as a Curative Agent for Tuberculous Glands.—Echlin S. Molyneux (*Lancet,* October 14, 1922) maintains that radium will cure even severe cases of tuberculous glands if the proper technic is carried out, without a waste of time and without leaving unsightly scars. The author's technic is the following: Square, flat applicators, containing fifteen mg. of radium bromide, two cm. square or twice that size, are used. The applicator is made of silver three mm. thick, over which the radium is spread and made to adhere by a form of cement. The applicator has over it a screen of one mm. of silver, then a layer of lint and finally a couple of layers of thin guttapercha tissue tied over the whole. The gutta percha tissue can be renewed for each patient. This applicator, thus protected, is strapped to the patient over the glands to be treated for four to eight hours with a one inch applicator and half that time for a smaller one. Two or more applicators may be necessary to cover the entire area of disease. The dose is administered twice a week at first and once a week when the glands are markedly retrogressing, but each case must be judged on its own merits in regard to the frequency and number of treatments necessary. Patients with early tuberculous glands recover the soonest, then those with suppurating glands; those with large masses of caseating glands that have not broken down take the longest time to heal. The treatment is continued until all the signs of disease have disappeared, leaving only tiny fibrous nodules. A cold abscess should be aspirated with a needle before beginning with radium treatment. The patient is not invalided in any way with this treatment. Only violent exercise is prohibited. The radium seems to have a general tonic as well as a local effect. Carious teeth or diseased tonsils and adenoids, if present, must be eradicated at the beginning of treatment.

DERMATOLOGY.

Treatment of Erysipelas by Vaccines.—J. Ronaldson Russell (*British Medical Journal,* July 1, 1922) reports an immediate improvement in the local and general condition of a patient suffering from erysipelas of the face after an initial injection of antistreptococcal vaccine (five million germs) and a second dose of twenty million germs. Uneventful recovery followed.

Röntgenotherapy of Carcinoma of the Skin.—G. Miescher (*Schweizerische medizinische Wochenschrift,* August 10, 1922) states that: 1. The superficial basal celled carcinoma (rodent ulcer) is easily cured by röntgenotherapy with the proper dose and a single exposure—about two to two and a half times the erythema dose. This dose is not harmful, unless too great an area is treated. 2. Hard rays are not necessary to effect a cure, provided the dosage is high enough. 3. The piercing ulcer and cancroid are also well adapted to röntgenotherapy, provided they are accessible and provided the entire area of the carcinoma may be subjected to a double erythema dose. The bone tissue, however, must be protected. Insufficient irradiation makes the prognosis worse. The single intensive irradiation is indicated in these forms even more than in the cancroid, as serial irradiation involves the danger of superficial healing and deep recurrences. The use of relatively weakly filtered rays does not always suffice and in some cases, therefore, a deep quotient resulting from irradiation through a strong filter is necessary. For the same reason, irradiation from a distance should be used. In extensive carcinomata of large portions of the soft parts of the face, the proper dose is important so as to avoid unpleasant consequences. The entire technic should be based on the biologically determined erythema dose of the individual for the various degrees of ray hardness. The physical criterion is the iontoquantimetric determination; with very hard rays (0.5 mm. of zinc, 1 mm. of brass, etc.), the Sabouraud and Kienböck procedures are not reliable. The statements of manufacturers of apparatus should not be relied upon. 4. There is no basic difference in the behavior of the various skin carcinomata toward röntgenotherapy and it is purely a question of technic. 5. There is no definite dose for carcinoma of the skin. 6. Irradiation of the lymph nodes is superfluous in basal celled carcinoma and in piercing ulcer.

Zinc Ionization as a Disinfectant in Local Sepsis, Illustrated by Its Use in Chronic Otorrhea in Children.—A. R. Friel (*British Medical Journal,* July 8, 1922) maintains that zinc ionization is an efficient method of sterilizing an infected cavity. If the sepsis is confined to the tympanum and the perforation in the drum is large enough to allow fluid to enter the ear, a complete cessation of the discharge is consistently obtained. If another lesion, such as a polypus or large granulations, is present, this should be removed first; complicating conditions, such as inflamed tonsils or adenoids, purulent rhinitis or sinusitis, or pyorrhea must also be eliminated first. In the series of tympanic cases observed, nothing but zinc ionization, with or without the insufflation of boric acid, was employed; in very slight cases, the insufflation of boric acid, without ionization, was used. The author also believes that zinc ionization is the remedy par excellence for the septic factor in endometritis, abscesses, boils, pyorrhea and accessible wounds and he suggests its use in sepsis of the uterine cavity following infection in childbirth. The treatment should always be administered by the physician himself.

Treatment of Psoriasis.—Hudelo (*Paris médical,* June 24, 1922), in the internal treatment of psoriasis, endorses Veyrières's procedure, viz., the giving of arsenic in small doses intermittently for long periods of time. Sodium arsenate is given in a 0.05 per cent. solution, two tablespoonfuls of which are taken daily in the middle of a meal, mixed with a large tumblerful of water. The drug is continued for three week periods separated by intervals of the same length. This treatment has seemed to the author useful in delaying and at times even preventing recrudescences of the disease. Massive intravenous arsenical injections, as advised by Ravaut, proved of little value in the author's hands, seemingly causing the lesions to acquire an inflammatory character. In some forms of psoriasis with rebellious and infiltrated lesions, unquestionable results have at times been obtained from intramuscular injections of mercurial compounds, such as the biniodide, yellow oxide, and calomel. Aside from arsenic, however, the most promising internal measure consists in the administration of sulphur. The writer praises the use of Pautrier's solution of sulphur, consisting of octahedral sulphur, five grams; cholesterinated oil, twenty grams, and eucalyptol, eighty grams. This preparation, which should be kept in ampoules protected from light, is injected into the gluteal muscles twice a week to the amount of one or two mils at a time. It causes little local disturbance and dose not induce fever. After the lesions have disappeared following this treatment, the injections should be continued at longer intervals for some time. The results cannot as yet be said to be greatly superior to those obtained from arsenical medication.

The Beginnings of Diagnosis

By JONATHAN WRIGHT, M.D.,
Pleasantville, N. Y.

It is not without interest, in the present exalted state of medical and surgical diagnosis, to take a survey of its beginnings. An enumeration, a mere catalogue of the instruments and the instrumentations, of the processes which enter into our everyday life as practitioners, would in itself transcend the space of volumes. It is probably true, indeed the best evidence we have points to the fact insisted upon by ethnologist and evolutionist alike, that neither do we now surpass antiquity in mental capacity nor does the average mental capacity with which children are born into a civilized world, either modern or ancient, surpass that of children born into a primitive environment. It is the social inheritance, not the germ plasm inheritance, that is the true endowment the infant meets the moment it opens its eyes in the modern civilized world, and it is the use society compels him to make of that inheritance which sustains the supremacy of a civilization. There is a constant demand, an ever increasing strain on his faculties, which sharpens his wits and broadens their field, deepens the draught of the vessel of mentality as it sets out on its adult voyage in life. Anything which enhances that acuteness, which broadens and deepens that mentality, is the product of the environment, and it should be the aim of those who have imposed upon them or impose upon themselves the herculean task of maintaining and guiding civilization constantly to keep in view and to multiply those environmental influences which do that. But in consciously or unconsciously pursuing this duty of aiding progress the substitution of instrumentation and the relief afforded mental exertion may defeat the end in view. For the sake of an efficiency to a material end we invalidate the human faculties which themselves are the mainstay of a complex civilization, however resistant and unaffected the precious germ plasm, the only immortal, immaterial, metaphysical, inconceivable product modern biology has introduced into a materialistic world.

This is practically the thought behind the argument Herbert Spencer used in the effectual resistance offered to the introduction of the metric system into the Anglo-Saxon civilization. He was one of the anxious ones watching over it and in his last years rendered himself a little ridiculous when he saw a perverse social world laying aside the processes by which the unfit perish in the struggle for existence. His was the last gasp of the old Manchester adjuration of every man for himself and the devil take the hindmost. He was solicitous for the continued mental capacity of his fellow countrymen and he objected to the metric system because it made figuring too easy. Much more of beneficial mental exercise is obtained by calculating in the cumbrous and complicated system of weights and measures we have, almost unaltered, as an inheritance from the civilization of ancient Egypt. If there is anything to this argument, and there are historical data which could be adduced in its support, we are muddling our wits with the multiplicity and the effectiveness of our instrumentation in diagnosis. The factory hand who does a thing a thousand times a day and the same small thing, the man who presses a button and lets machinery do the rest, the man who lets the colorimeter take the place of his eyes and the calorimeter and the thermometer take the place of his hand, the man who uses the stethoscope and even the osphresiometer instead of his ears and his nose, may indeed be handling the instruments of his own destruction. This may be an argument full of fallacies and I am afraid it is, but let us pause for a moment in our historical studies to remember that primitive man had none of these things and ancient civilized man only had them in a quite negligible supply so far as the argument goes for the greater acuity of his natural faculties.

These considerations, though largely hypothetical, are not entirely without coherence with what we have to consider in the study of the beginnings of medical diagnosis. In the first place, as always in going back to prehistoric or early historical things, especially in the history of science, we meet with a lack of differentiation which we must guard ourselves against regarding with contempt and neglect.

Copyright, 1923, by A. R. Elliott Publishing Company.

Approaching our theme more nearly we come to realize that the savage does not think at first of etiology in a selfconscious way at all, so far as a specific application is concerned. It is his intuition, what he has from his social environment, which guides him in such appreciation of it as he has.

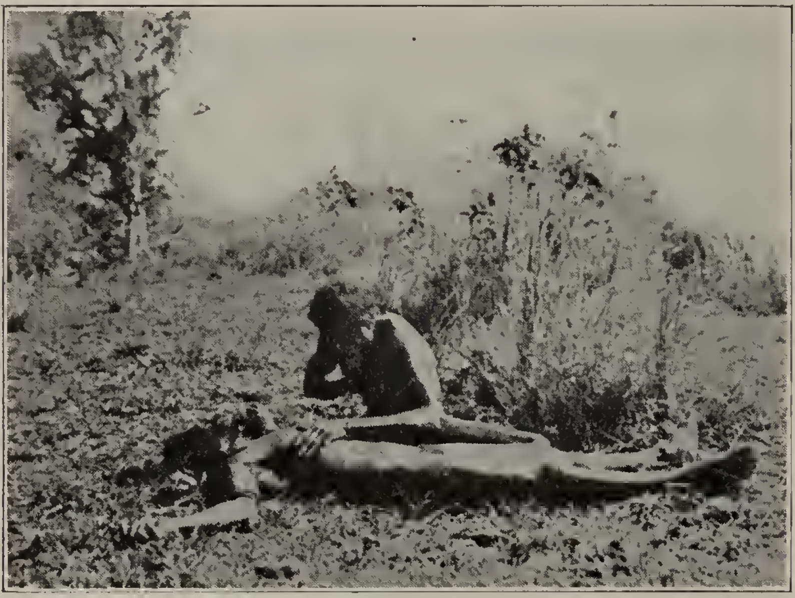

Fig. 1.—Medicine man rubbing his hand under his armpit to secure moisture to rub on the patient. (Kakadu Tribe.)

Something has gone out of the unconscious man. It must be a part or a whole of the world spirit which animates all things that has left him, and in Australia, like Elijah, he attempts to blow the pneuma back by placing himself mouth to mouth with the patient, or as in Egypt once, or as among the Indians of our North Pacific Coasts, he tries to blow air into the anus. Historical times acquired a bellows for this purpose. Or some evil spirit has got into the man and the doctor tries to suck it out. (Figs. 1 and 2.) It is easy to show the patient anything the doctor can hide in his mouth anyhow. Therapy follows so close on diagnosis we can scarcely separate the two. Both are entirely dominated by cosmic theories.

Several years ago in this journal (August 4-11, 1917) I drew attention to this matter, but I shall only repeat the quotation I then made from Dobrizhoffer's account of the method of diagnosis among the Paraguayan Indians in the Eighteenth Century: (1) "At his first coming, the physician overwhelms the sick man with a hundred questions: 'Where were you yesterday?' say he, 'What roads did you tread? Did you overturn the jug, and spill the drink prepared from maize? What? Have you imprudently given the flesh of a tortoise, stag, or boar, to be devoured by dogs?' Should the sick man confess to having done any of these things, 'It is well,' replies the physician, 'we have discovered the cause of your disorder. The soul of that beast having entered your body torments you even now, and is, alas! the origin of the pains you feel.' "

Let us glance a moment at the method of the old Egyptians in the Papyrus Ebers, the beginning of the vademecums of the physician,—as to the motion of the heart. We get at once on the trail of the Oregon Indian. When the breath goes in at the nose it goes to the heart and the rectum and such like vessels of the body and one hears it rumbling there and it is the rough wind cuts the patients insides and wherever you lay your hand on the vessels you feel the beating of the heart. When the heart sucks in water too there is trouble. Even though under one's hands this is not always evident, yet they are full of water and air. When there is bitterness in the heart the *rô-ab* (abdomen) grows large both to sight and feeling. We see the "laying on of hands" has ancient history behind it. Again we find theory interfering with diagnosis and we conjecture it is apropos of the pneuma, the rough wind. "If the heart feels a mawkishness, it is the bitterness of the heart dependent upon an inflammation of the rectum." It is not difficult to recognize across 3500 years gastrointestinal disturbances, heart burn, flatulence, in these diagnostic lessons the old Egyptian practitioner is giving to the profession of his day. In the Atharva Veda (2) of the Hindu the practitioner for bowel trouble "blows upon the rectum of the patient." In the Papyrus Ebers when the heart is sick he is instructed to blow through the hollow of his hands so the breath or pneuma penetrates the rectum, (3) as we gather from Joachim's much criticised rendering of the text and from Hearne's *Trvaels* Bancroft (4) gets his authority that among the North American Indians of the northwest coast for inward complaints the doctors blow zealously into the rectum or adjacent parts. I repeat this scrap of therapy from what appeared in these columns in another connection four or five years ago in order to preserve the contact of savage life on another continent with the ancient civilizations, and we see there as well as in Africa and Australia the diagnostician working on a theory basis in intimate connection with primitive pantheism. We meet with something more familiar in the manner the practitioner of old Egypt is advised to say when a little at loss to meet the demand of the patient for a diagnosis who has a cervical growth: "He has a tumor scrophulosus of fat causing an interference with the atut in his neck." This ought to bottle up any inquiring patient.

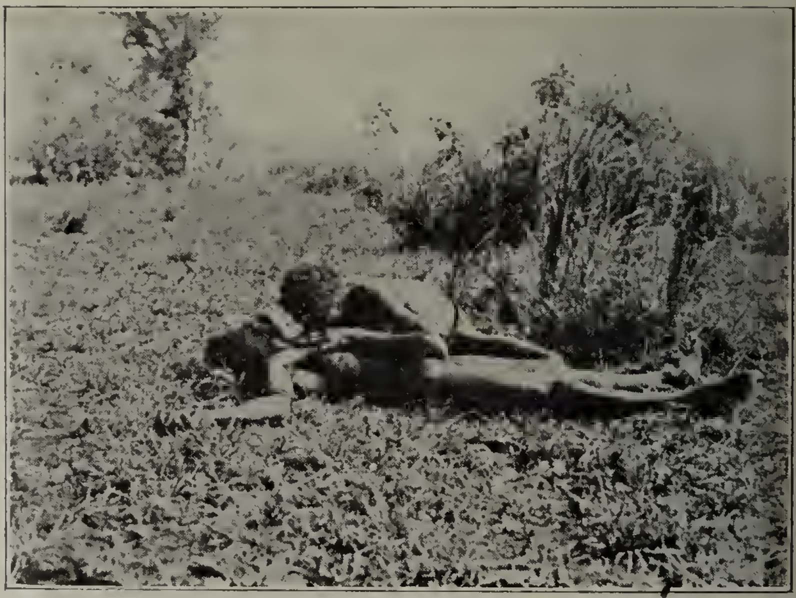

Fig. 2.—Medicine man sucking and massaging patient to withdraw girl magic. (Kakadu Tribe.)

Then we turn from oriental fakirs and occidental medicine men to Hippocrates. In some way the author of *Fractures and Dislocations* seems responsible for the book on the routine of the physician, the Iatreion or Office, the surgery of the physician.

We will find a very striking advance in the discipline if not the technic of the diagnostician in the thousand years or more which elapse between the Papyrus Ebers and the Hippocratic Corpus. "Investigate from their origin the resemblances and the differences between the diseased and the usual state of health of the patient, most marked and most easy to recognize by their manifestations; these it is furnish us with our opportunities for observation. Seek out what you can see, touch, hear, what you can find by looking, feeling, listening, smelling, tasting, and upon these turn the powers of your mind —in short use all the powers of your faculties." Could anything more tersely and completely epitomize instruction for the diagnostician in training? But to turn back to my introductory paragraphs, can we hope that we are able, pampered by physics and chemistry as we are, to use all the powers of our faculties; is it possible for us to be keyed up now to the ancient pitch of Hippocrates in all these senses and mental capacities, bare then of all accessories to assist the former, and unsupported now by the dialectic and analytical exercises which trained the latter? Our gain has been enormous, our achievements are astounding, even when we discount the innate vanity every generation carries for its ephemeral triumphs, but let us not be blind entirely to what we have lost, let us not lose altogether or too soon the point of view of the Spencerian doctrines.

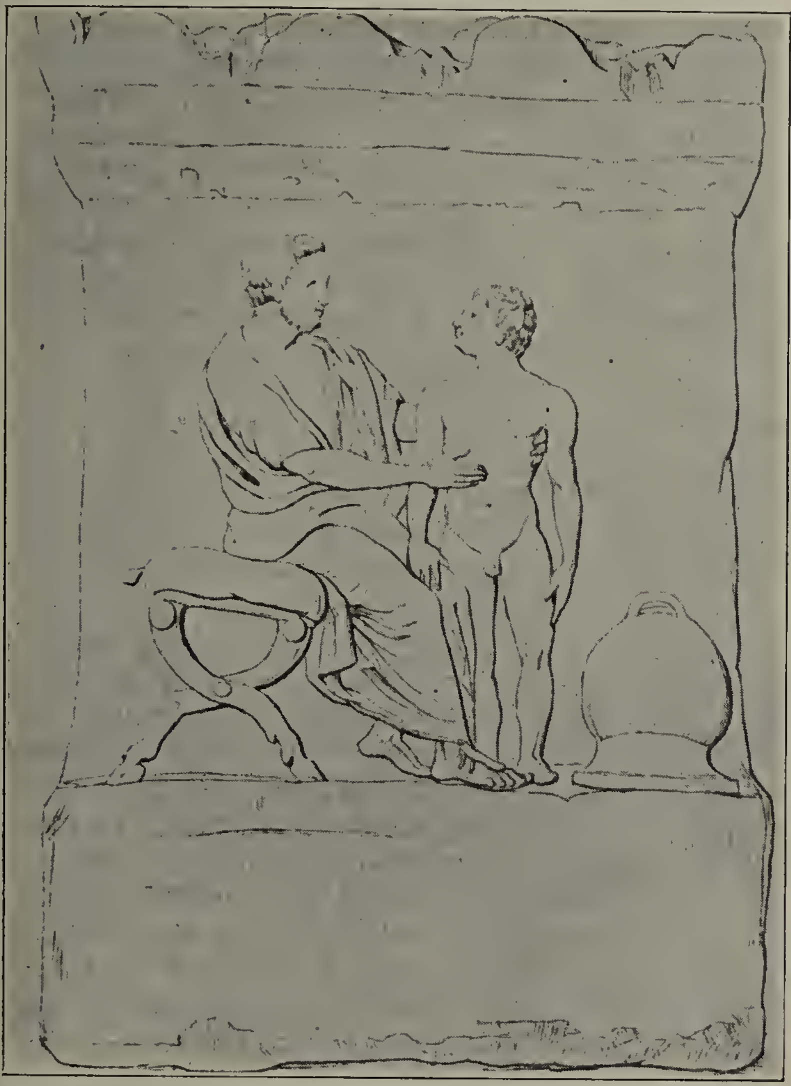

Fig. 3.—The physician Jason diagnosing a patient. From a grave monument at Acharnæ.

In the discourse of Hippocrates, at every turn of the phrase a sermon is wrapped up in a word or two. In Cicero we meet with the reflection of these pregnant precepts laid down by Hippocrates. He refers (5) to the method of diagnosis of the doctors of his day, nearly two hundred years before Galen was born. If he is attentive to his duty, he says, before he attempts to give medicine, he must know not alone the disease with which he is confronted, but the habits of the patient when well and his constitutional idiosyncrasies are to be investigated. This is a mere echo of the phrase as to resemblances and differences exhibited by the patient in health and disease and this is the first thing Galen seizes upon for a theme.

The opening sentences in the Hippocratic book on the surgery of the doctor the most inexperienced of commentators must, at the earliest date, have been able to recognize as capable of the greatest expansion, but the commentaries of Galen (6) are the first which have come down to us and by far the most extended. His diffuseness in recording his clinical experiences has been unequalled and scarcely less his acuteness of observation and the thoroughness with which he explored all the resources of Hippocratic art, and it seems singular we can find no reference to the auscultation of the chest. We read here his questioning and his cross examination of a patient in getting the account of an accident requisite fully to elucidate the physical findings in a case of dislocation downward of the head of the humerus. We get the prolixity of which he himself apparently is aware as a failing of his own, but in spite of himself his garrulity, especially when engaged in chronicling his successes, runs away with him. The first sentence in regard to differences and resemblances sets him off to remind us of Hippocrates's immortal description of the facies of death and to our disgust and annoyance he proceeds to analyze it and to point out wherein it differs from the facies of health or of a passing indisposition. It is like taking down a dictionary to explain a witticism. The perfume of it vanishes at once.

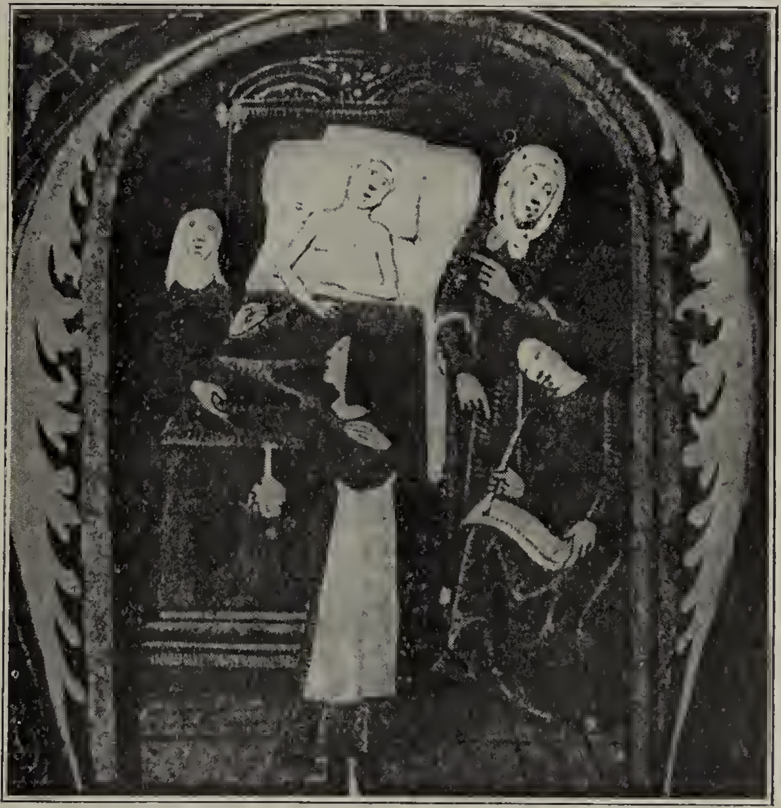

Fig. 4.—Keeping a record of the case. From a mediæval Latin manuscript of Galen.

Yet when Galen rises to a specific description of the rational signs of a dislocation of the shoulder joint it is perceived that his lack of humor and his want of artistic perception of what may be mentioned and what had better be left for the reader on which to exercise his own mental faculties, in no way contravenes lucidity in language or prevents him from making evident his quick and accurate powers of observation. One needs only to peruse his commentaries on Plato and Hippocrates to see with what gravity, with what lack of this artistic quality, he fills in the gaps these immortals left because of the artist's intuition—out of courtesy indeed to the reader, out of compliment to him, an implication of his perspicacity grateful to his selfesteem—for him to fill in. When Galen comes, either as an observer of clinical facts or even as a writer to record them, he is instructive and illuminating and his very garrulity has that species of attractiveness which is inherent in pure narrative, even when devoid of any semblance of imagination or of art. His faults as an artist, even his lack of taste as a gentleman, as well as the fruits of his active mind, he handed on to the generations who followed him for more than a thousand years and he preserved for them the fruits of minds greater than his own and taught them a reverence which has stood our civilization in good stead.

As to the case of dislocation of the humerus he tells how some chiropractors failed and he succeeded in diagnosing the state of affairs because the former had failed to elicit from the patient the fact that he had bruised one shoulder before he had fallen on the other. They had failed too to feel in the axilla. In short they had failed, and this is the criticism of leaving too much to the reader's perspicacity, they had not thought of following out for themselves the details of the axiomatic and all embracing catholicity of the Hippocratic discourse on diagnosis, if they had ever read it. They lacked not only the acuteness of observation which distinguished Galen, which might have been the fault of the gods and not their own, but they had not his thoroughness of method with its meticulous detailed care and scrupulosity, which training and industry might have given them.

I have incidentally alluded to the passage in Hippocrates concerning hydrothorax (7a) which so attracted the attention of Littré and the contemporaries of Laennec, indeed of Laennec himself. We could almost believe the Jason in the illustration (Fig. 3) was thinking of physical diagnosis and feeling for the fremitus of the friction of pleural surfaces or spying out the resemblances and differences in the respiratory movements of the two sides, as Galen taught should be done for the shoulder joint. "If you apply your ear to the chest," Hippocrates says, "and listen for a long time there is a noise as of vinegar bubbling." Again as to a patient with pyothorax (7b), "Set him on a firm chair, let an assistant take him by the shoulders and shake him and then do you apply your ear to the chest that you may know on what side the trouble is. . . . If the fluid is so thick there is no fluctuation and no noise is made in the chest, but the patient has a rapid respiration, a little cough and the feet swollen, be sure, nevertheless, the chest is full of pus." All the medical world in France, after the Napoleonic wars, had been moved by the researches of Laennec (8) on the auscultation of the chest, and by the time Littré was engaged in giving us the standard text and translation of Hippocrates, physical diagnosis had made great advances and had excited universal attention in the medical profession. Laennec had drawn attention to the passages I have already quoted, but Littré insisted that a sentence in a previous paragraph (7c), "the lung falls against the side of the chest," shows that the reference to "vinegar bubbling" is a notice of the crepitant râle. Any country boy would recognize the sound, having heard it, when straw in mouth to stick through the bung hole, he has laid his head against the barrel staves behind which the cider is fermenting. That was the sound Hippocrates was referring to. The cough and the distress in breathing we find described "and a noise is heard as of leather." Just what sound Hippocrates heard when the patient was shaken Littré is a little doubtful about, but we know that with the sound of succussion is often heard the sound of bubbling vinegar and of creaking leather if the ear is held against the chest long enough. There cannot, however, be any doubt whatever as to the general conclusion that Hippocrates was familiar with the abnormal chest sounds in disease of the lungs and their membranes, and to have referred thus plainly, but almost incidentally to them, we may well believe could only have been ventured upon by a physician who had long had opportunity to note the phenomena, and this bit of knowledge of diagnosis must have been widespread and well known. Otherwise it would, one must think, have received almost as particularized a notice in Greece at the hands of Hippocrates as it did in France two thousand years and more later.

Although Galen fully appreciated the importance of using all the sense in the service of diagnosis, as Hippocrates insisted, even though we have from Galen no commentary especially on these passages, it seems remarkable that such a thing perished after once being well known in Greek medicine, for, as Galen insisted, "the first of all things worthy of attention in the art of medicine is the diagnosis of disease." (Fig. 4.)

Pluralism in Medicine and Therapeutics

By H. A. BOSMA, M.D.,
Groningen, Holland.

In daily life we see that fairly dependable regularities of sequence occur. It is these regularities that have suggested our law or supposed law of causality. If a stone of a certain weight is flung against a window pane with a certain force, the glass breaks, and we expect that glass of the same thickness and equal constitution will be broken every time a thrower with equal force flings a stone of the same weight. On this hypothesis medical science—granted there is such a thing—also has built its temple. Hypothesis: Why must there be a recurrence of events?

In everyday talk we frequently use the word cause, meaning thereby something like the event, the force, the thing that acts, operates, produces an effect, all anthropomorphic phrases since, strictly speaking, only human volition can produce an effect (1). Science abounds with metaphysical conceptions and terms; glibly we speak of action, interaction, influences, causes, affinity, attraction, factors, and so forth, whereas the only thing we truly know is our own feeling of causality. But this cannot be avoided; it is part and parcel of the mystery of being, and it matters not a whit, since science is chiefly for practical purposes and the acadabra of its tools is immaterial, so long as it leads to predictions and aids the human being in better adapting himself to his ever changing conditions of life. Generally speaking, we mean by cause the spark that ignites the train of gunpowder leading to the hidden depot of dynamite, the last weight that tips the scales. By habit of mind, we medical men are also inclined to picture one particular agent that is doing the mischief. Fifty years ago doctors attributed a medley of diseases to "cold," as the layman, not altogether wrongly, still continues to do at the present time. Then bacteria got into the limelight of medical attention, leaving the socalled cold in the dark. For many years the mind was *eingestellt* (set) on microbic action, until it was discovered that not every one gets tuberculosis, though all are infected. And constitutional pathology revived again. Thus the practitioner is apt to fall from one onesidedness into another, until he grasps the fact that diseases depend on an ensemble of conditions, or better, are due to a "constellation of factors," a term introduced into pathology by Prof. Tendeloo of Leyden in 1913.

In the recently published Dutch edition of his *General Pathology* written in German (2) Tendeloo discards the word cause altogether except in the sense of constellation. Every pathological change depends on a constellation of factors, both internal and external. Yet a constellation is more than the sum total of factors, one factor may influence another, or they may mutually influence one another, and this is also a part of a constellation. Several observations show that each factor has but a relative value, dependent on the constellation of which it is a part. Think of the different effects of hot air, whether dry or saturated with moisture. Of course, what is usually designated as the cause of a disease, be it a microbe, an exogenous poison, or an endogenous poison, also belongs to the constellation. In proportion as one disease producing factor is stronger, other factors lose in significance. A trifling force is needed to break an exceptionally brittle bone; a skyscraper, coming down on a man with the most solid osseous system on earth, will crack every shaft of his anatomy into fragments. But, if the morbid factor is relatively small, as so often is the case, then the oscillations of other factors of the constellation acquire a tremendous importance. It is wrong, giving rise to ambiguity and leading to therapeutic errors, to call the most conspicuous factor the cause of the disease, as, for example, a poison or an infective microbe. For pathogenic germs thrive only in a suitable soil and a poison requires a certain susceptibility to its action.

Let us remember this: Babies and old people stand opiates badly, herbivorous animals tolerate chloroform far worse than carnivorous, the maximal dose of atropine given to man is one mg., whereas one gram injected into a rabbit does not kill the animal. We consider ten mg. of morphine given hypodermically to a man of middle age, a safe dose, but I know of a practitioner in this country who, very soon after the injection of this amount, had to deplore the loss of two by no means moribund patients, and who, ever since, hesitates even to give a hypodermic injection of morphine in half the dose that is considered safe. Manquat witnessed the death of a man twenty minutes after the injection of one c. c. of pantopon; another man of sixty-five succumbed after taking 0.5 gram of antipyrine and a child of five died after 0.3 gram of antipyrine had been given in a suppository. He also witnessed two serious mishaps after the ingestion of 0.5 gram of pyramidon. That our average doses are, on the whole, still too large is the opinion of clinicians like Vaquez and Fessinger.

Why do these things happen? We do not know. We have no inkling of a suspicion even, since the various constellations met with by these poisons are unknown to us. Recent experiments may offer a clue. Strychnine, we know, has an elective action on certain portions of the nervous system. A few investigators found that it is held in combination by cholesterin, perhaps absorbed and rendered ineffective by it. We also know that the quantity of cholesterin in the blood varies in different individuals and has its fluctuations in the same individual. Thus we understand, in this case at least, why strychnine may be more poisonous to one person than to another. Oxidation, reduction, adsorption, substances in the nascent state, may all be factors that determine the ultimate fate of a poison ingested. The possibility of an internal secretion being decomposed, held in combination, weakened, intensified, or quantitively changed, should be thought of before jumping at once to the conclusion of a hypo, hyper, or dysfunction of an endocrine gland. All we know positively is that we know positively very little.

Now, if for a full understanding of a disease it is imperative to find out all the factors that make up the constellation, shall we ever succeed in knowing the etiology of diseases? Of quite a number, I believe, we never shall; we shall only arrive at a higher degree of exactness without ever attaining complete knowledge. But then we are but in accordance with the whole trend of modern science whose cocksureness and completeness is an illusion of the past. Everywhere approximate formulas take the place of absolute solutions, and the variable pushing aside the invariable more and more a summation of differences is observed and, where identity was thought to be present, only analogy turns out to exist. Science cannot find out, nor fix all conditions of a natural phenomenon. Hence, the more a man really knows, the more reluctant is he to make a prediction or a prognosis. The scientific wording, too, bears this out. It is timid in expression. The utterances of our truly scientific men, in contradiction to charlatans of every kind, are not very positive; they make their statements with all sorts of restrictions. They frequently say *ceteris paribus* and their pages abound with such hesitating terms as, it would seem, probably, perhaps, to all appearance, left for future research, and so forth. Human physiology and pathology are in this respect no exceptions to the rule. Every individual, they teach us, is a fresh problem, each a living link with blood and structures affected by a long ancestral chain; of no two persons are the fingerprints exactly alike; the chemistry of bodily cells is peculiar for each tissue; the Blazek twins, though united in body, had different passions and desires and their different susceptibility to disease became at last fatal to both. We are told nowadays to treat patients along physiological lines, but in the preface of a book of this character (3) which, by the way, I should wish to be read by every practitioner, we may read this significant passage: "When I reflect that I am now teaching the exact opposite to many of the views held ten years ago, I feel that physiology can only come to the aid of medicine with becoming modesty and without overweening dogmatism." Thus, a general pathology, useful and indispensable though it is, must always remain a rather rough scheme; a special pathology is a little more accurate but schematic still; a physiology and pathology of an individual comes nearest to truth.

The present drift in physiology and pathology is ever more towards physiochemistry and colloid chemistry and the facts of late years, brought to light by international cooperative research, are amazing and bewildering. And at least one characteristic point these investigations have revealed; the immense complexity of the living organism. It certainly does not seem as though still deeper penetration into vital problems will result in simplification of our views; on the contrary, we increasingly perceive more multiplicity and subtle shades of difference where oneness and invariability were assumed or promised. And yet, these biochemical studies do not altogether leave the final impression that all is chaos and confusion, for indeed we here and there perceive useful adaptations, correlations, a tendency towards equilibrium, though in other times we are vexed with Nature's stupidity when she is overshooting the mark and defeating her seemingly useful purpose. Variability once more.

Now it may be asked, what have these reflections to do with the practice of medicine? Just this much. Knowing that most diseases, if not all, depend on a constellation of factors, are due to a plurality of causes, it is incumbent upon us, as hygienists and healers, to aim preventively and therapeutically at as many factors as we may lay our hands on. Socalled causal treatment is too often firing one rifle, loaded with one cartridge, at one malefactor. True causal treatment is attacking any and every factor of the disease producing constellation; it is sagaciously handling the Browning and, when at our wit's end, heaven pardon me, using the shotgun. True, this treatment may become plainly symptomatic, but what about that? Many a physician, especially when young and aspiring to be scientific or nothing, feels secretly guilty of quackery, if he is not getting at the cause and only treating symptoms. This is often a misplaced selfaccusation, based on false logic. Not seldom it is difficult to locate the primary seat of disease; we only notice disturbances of various functions, in some cases there is no primary seat, nor any seat whatsoever. A strong emotion reverberates throughout the whole body, affecting every function for good or for evil. *L'organe crie sa souffrance, avant d'être lésé.* In fact, we often must treat symptoms even when we know exactly the primary seat of disease. There is the elderly patient with insufficient heart action; he is dyspneic, and his difficult breathing is aggravated by the mucus in his badly congested lungs. Of course I give digitalis, but I add to my potion some potassium iodide, caffeine, sodium benzoate and spiritus ammoniæ anisatus and I know from experience that this combination will give my patient more relief than the digitalis alone. I also attend to his stomach and bowels, although I know the primary mischief is in his degenerated heart. Let us not forget it; it is symptoms that bother the patient; to him symptoms are his disease. And by treating his symptoms also we may do him a world of good and by doing so we are acting in a highly scientific manner, for symptoms are, or may become, causes at any time.

But we must be on our guard. We by no means treat symptoms always. We certainly do not commence antipyresis with every elevation of bodily heat; we do not suppress every cough; do not stop every diarrhea; do not check every nosebleed. We abstain when Nature is wise, interfere when she is stupid. We always combat symptoms that visibly endanger life, we do not heed those that aid the *vis medicatrix*. This is what marks the good doctor; his knowing when to act, when to let go. But, whether we deal with causes, with symptoms, or with both, our art is always pluralistic, never monistic, if I may be permitted to borrow two words from contemporary philosophical thought. The human body is a psychophysicochemical cauldron, chief among which is the psychical factor. Human physiology and pathology are not those of rabbits and cats. In not a few diseases emotional influences play a predominant rôle. Our ever increasing knowledge of endocrine glands and the autonomic nervous system begin to throw light on the mechanism between body and soul. And it is quite certain that the physician's personality and his suggestive influence are, in the treatment of any disease, of the utmost significance.

Physicians of the past were well aware, too, of the mind being an important disease producing and also curative factor; besides experience had led them to adopt complicated prescriptions and to use decoctions and infusions of the whole complex flower and herb. True, their therapeusis was often sheer handling of the shotgun and, knowing little pathology, they were hitting right and left at all symptoms. But incidentally they must also have struck primary causes, for they certainly cured many of their patients. These old doctors were by no means fools. Their minds not being crammed with all kinds of theories and conceptual thought, they became the better observers and in clinical description and subtle differentiation have in our time not been surpassed. Now, the complicated prescription in itself is not to be condemned; in accordance with our pluralistic conception of cause and the significance of symptoms, the too simple prescription is neither scientific nor most efficient. And I believe a return to more complicated, but well reasoned out prescriptions, adapted to the ever changing reactions of each individual patient, is in harmony with what physiology and pathology teach us. This does not mean a reverting to the old shotgun prescription, based entirely on empiricism, but an improved modification of it, for as the old pluralistic philosopher and mystic Blood of Amsterdam (N. Y.) truly said: "The same returns not save to bring the difference."

The Treatment of Severe Diabetes with Insulin*

By NELLIS B. FOSTER, M.D.,
New York.

To begin by estimating the number of calories which a patient needs to maintain weight and energy and then to compute a balanced diet which will furnish this amount of energy, may seem a fantastic method of treating diabetes. However, this is precisely what is being done today in the clinics where iletin is being used. Up to a year ago it was necessary in all severe cases of diabetes to reduce body weight and energy in order that a diet, too meagre to support life in a bulk of tissue, might do so in a smaller mass. In other words, it was necessary to reduce the individual to meet his scanty food supply and of course this resulted in invalidism and mere vegetative existence, terminating either in coma or death from inanition.

The specific action of insulin is notable in its effect on the sugar of the blood. After a dose of insulin the blood sugar falls. The amount of decrease is to some degree dependent upon the size of dose of insulin given, but also upon the severity of the diabetes. Individuals react differently in their quantitative response, although the general effect is alike in all. (1)

It becomes necessary then to determine with some precision the appropriate dose for each individual diabetic. An overdose may reduce the blood sugar too much and cause symptoms which are spoken of as insulin shock. This condition arises if the blood sugar falls below about .05 per cent. Coma may develop and death occur. These critical symptoms can be combatted successfully by administering promptly small doses of glucose intravenously. Recognizing this possible source of danger and understanding that a dose of ten units of insulin may have much more effect in one individual than in another, it is evident that the initial period of treatment must be conducted with some degree of exactness. In the New York Hospital we have had considerable experience and have had no case of insulin shock, and in other respects the results have been gratifying beyond expectation.

When a diabetic patient is to receive insulin the diet should be controlled in order that the amount of sugar entering the blood be uniform from day to day. With a patient on such a diet the first effect notable after insulin treatment is started is the subsidence of the glycosuria. This may be slow, requiring several days if the dose of insulin be small, or it may be rapid. I have seen the sugar disappear from the urine in a case of diabetic coma within twelve hours. The dose then was, of course, large. After the urine is free of sugar the only guide for dosage is the blood sugar. From the patient's point of view the effect of insulin is surprisingly prompt. Not infrequently within a few days there is a sense of renewed strength and energy which cannot be entirely accredited to psychological effect. This effect is quite easily understood since the sugar, which before treatment was lost to the body and excreted in the urine, under the influence of insulin is utilized for energy. In severe diabetes the urinary glucose may represent twenty-five per cent. of the energy of the food taken.

While an estimation of the degree of severity of a case of diabetes is not an essential preliminary to treatment of any kind, it is, however, often useful, first as a guide to the amount of insulin probably required, and, second, it is a basis for comparison in future observation of the patient. To meet this need we have used a rapid method of tolerance estimation which we feel has certain definite advantages. Our standard diet is milk. In the first place milk is a safe diet for a diabetic during the first few days of study. Next, it is fairly uniform in composition and is easily measured. We give one litre of milk a day for three days. This diet represents forty-three grams of protein, forty of fat and fifty-one of carbohydrate, according to the analysis of our milk. During the third day of this period the urine is collected as a twenty-four hour specimen. The total glucose and nitrogen are estimated in this specimen. Since a patient may catabolize more protein than the amount taken in his food, we cannot use the food protein as a basis for estimating the sugar derived from protein. It is well known that severe diabetics may catabolize their own muscle tissue. For example, during fasting there is a daily excretion of five to ten grams of nitrogen in the urine and this represents from thirty-one to sixty-two grams of protein. The urinary nitrogen tells the actual protein catabolized regardless of its source. Each gram of nitrogen equals 3.6 grams of glucose derivable from protein.

---

*An address delivered before the Syracuse Academy of Medicine.

Nitrogen x 6.25=protein.
58% of protein is converted into glucose.
6.25 x .58=3.6.

Let us use a concrete case in which milk was the only food given during the tolerance test. One litre of milk in this instance contained protein, 33 g.; fat, 41 g.; carbohydrate, 51 g. The twenty-four hour urine contained 6.21 g. of nitrogen and 63 g. of glucose. It is at once evident that this patient is excreting more glucose in the urine than there is carbohydrate in the food. What is this tolerance?

(N) 6.21 x 3.6=22.3 g. (glucose from protein).
The available carbohydrate in the diet is the 22.3 g. (from protein) + 51 g. (sugar in milk)=73.3 g.
Tolerance=73.3—63.9 (urinary glucose)=9.4 g.

This computation is made from one of our cases and represents a very severe type of diabetes. It must be evident, too, that no measure of tolerance, i. e., severity, is possible without taking the protein metabolism into consideration.

As I have already said, the determination of the tolerance of the patient is not absolutely essential but it is of great interest for future comparisons. Now, in building up the diet, attention is first given to the amount of protein food because protein is the indispensable food for which no other can be substituted in the body. The ordinary processes of life cause a breaking down of cells and of tissues, and these cells and tissues must be replaced. The peculiar element in all cells is protein. The minimal amount of protein required by an adult is approximately 0.6 gram to the kilo of body weight. It is advisable that there be some margin and on this account a slightly larger amount than 0.6 gram is desirable. We usually estimate that about 0.8 gram of protein to the kilo of body weight is the correct ration.

Suppose then, that the patient weighs one hundred pounds, which is equivalent to forty-six kilos. Thirty-seven to forty grams of protein would be the first determination. If the patient is to be on insulin treatment, we need not be too economical in the amount of protein allowed.

In the beginning, we may decide on sixty grams of carbohydrate as the initial allowance. The amount of fat to be given can be definitely determined since the complete combustion of fat to carbon dioxide and water is dependent upon the amount of carbohydrate that is burned at the same time. It has been determined in the last two years that one gram of carbohydrate will effect the complete combustion of 1.5 gram of fat. In estimating the carbohydrates we must take into consideration, also, the carbohydrate derivable from the protein. In the calculations given above, 23.2 grams of carbohydrate result from protein disintegration (40×58 per cent.). 23.2+60 (the carbohydrates in the food)=83.2, total carbohydrates of food.

Using this figure as a basis for our carbohydrate-fat ratio, the fat of the food should total about 124 grams. This diet will be equivalent to about 1,500 calories. The adult diabetic who would be, in all probability, underweight if he weighed but 100 pounds, would have a metabolism below normal. On the basis of thirty-three calories to the kilo of body weight he would not require more food than this. In other words, the food represented in such a diet formula as protein forty grams carbohydrates sixty grams, fat 124 grams, would represent a maintenance diet and would be an advantageous one with which to start treatment with insulin.

If the tolerance of such a patient were as low as the case illustrated above, of course there would be a marked glycosuria unless insulin were given, but with the aid of insulin the glycosuria can be easily controlled. To illustrate the considerable increase of calories which may result in a diet by even slight increases in carbohydrates, take the following table:

TABLE A: DIET COMPUTATION.

Protein	*Carbohydrate*	*Fat*	*Calories*
24 g.	30 g.	85 g.	980
24 g.	40 g.	108 g.	1128

You will notice in this table that the proteins are the same in both diet formulæ, that the carbohydrate is increased by ten grams in second, but on account of the considerable increase of fat made possible by this slight increase in carbohydrate a marked increase of calories results. It is true that in many cases fat can be given in the diet in excess of the ratio of 1.5 grams of fat for each gram of carbohydrate without there developing ketonuria or any evidences of acidosis. This is due to the fact that diabetic patients who are very markedly undernourished have the power of storing fat in exceedingly large amounts. The tissues seem, under some circumstances, to imbibe fat in something the same way that they may imbibe water after periods of water deprivation. Fat that is stored does not enter into the metabolism; that is, it is not burned, and on that account does not act as a precursor of the ketone bodies.

There remains to determine the amount of insulin required to control the glycosuria which will probably develop in severe diabetes when the patient is placed on a diet like that outlined above. It is impossible to tell in the beginning how much insulin will be required. On this account, one usually begins with rather smaller doses than it is expected will be needed. If the urine is carefully watched during the first two days, *not as twenty-four hour specimens but each separate voiding,* a guide may be had to the effectiveness of the insulin dosage. One may be sure that the amount given is not excessive so long as sugar remains in the urine. The moment, however, that sugar disappears from the urine there is no guide except the blood sugar. In beginning insulin treatment, one might decide on a dosage of five units three times a day, to be given about half an hour before meals. If it were found on observation during subsequent days that considerable amounts of sugar were being excreted in the urine, then the dose of insulin should be gradually raised. On the other hand, if, after twenty-four or forty-eight hours, sugar should disappear from the urine, then the dose of insulin must be promptly diminished, or possibly it may have to be stopped entirely for a period of six to twelve hours, at the end of which treatment is reinstated on a smaller dosage as sugar again reappears in the urine. Considerable experimentation is required with each case in order to determine just what amount is necessary to care for the diet and not allow more than traces of sugar in the urine and at the same time not be excessive enough to run the risk of producing a fall in blood sugar to a dangerously low level. There is no rule that can be given in determining this dosage since with some cases five units seem to have as much effect in the combustion of carbohydrate as twenty-five units have in another case.

It is notable in what has already been said that the iletin treatment has caused a wide departure from the standards of scientific treatment which prevailed a year or so ago. Under the old treatment, we regarded it as a mistake to have any sugar in the urine. Some authorities went so far as to endeavor to secure normal blood sugar as well as a sugar free urine. It became evident when we began to use insulin that we must abandon the attempt to maintain a normal blood sugar because the latitude between the normal, fasting blood sugar of 100 to 120 milligrams, and the dangerously low blood sugar of 50 milligrams, was so narrow that slight errors in dose or slight changes in the patient's condition might at any time precipitate insulin shock. In fact, that is what did occasionally occur and caused the change in the procedure. As a result of this experience, many of us now feel that with patients on iletin treatment and not under constant observation, the safest condition is to have constantly a trace of sugar in the urine, the ideal being about 0.1 per cent. The reason for this "buffer sugar" is that when this is present we are confident that the blood sugar is something above 160 milligrams (the renal threshold). Certainly, in many cases, it may be considerably above this. Whether this is a desirable state of affairs in itself, is questionable. But we are presented with the dilemma of running the constant danger of having a patient manifest shock or the alternative of countenancing a persistent glycosuria.

Insulin can be given, as I have said, three times a day before meals. The reason for selecting this time is in order that the absorption of the insulin into the blood stream will coincide approximately with the increase of blood sugar produced by the intake of food. In some patients we find that two doses of insulin a day, one before breakfast and one before supper, meet the desired end, and in a few patients we have succeeded in reducing the dose to one single administration, either in the morning or in the evening. It is obviously desirable to make the number of injections as few as possible, not only on account of the convenience to the patient but also because there are relatively few skin surfaces of the body suitable for hypodermic injections and when these are being given two or three times a day, the problem of a suitable site may become serious.

I wish to give two specific cases which illustrate not only the efficacy of insulin in the treatment of severe diabetes but also tell better than any explanation can do the method of its use.

CASE I.—The patient, M. T., had been a severe diabetic for several years. He was a man forty-two years old and had gradually lost tolerance in spite of intelligent and faithful care. At the time he came under our observation he weighed eighty-seven pounds. His tolerance, as estimated according to the procedure outlined, was thirty-three grams. On a diet containing forty grams of protein, forty-five grams fat and fifty grams carbohydrates he excreted forty-two grams of sugar in his urine.

CHART I.

	Diet				*Units*	*Urine*		*Blood*		
Jan.	*C*	*P*	*F*	*Cal.*	*Iletin*	*G* *Gram*	*K*	*G* *Mg.*	*CO*$_2$	
1.	50	40	45	760	0	43	+	272	48	Ur. N=7.2× 3.65=26
8.	20	40	100	1140	9	8.7	0			26+50=76—43=33 T=33
9.	20	40	100	1140	9	8.5	0	185	54	
11.	20	40	100	1140	9	0	0			
15.	40	50	120	1440	15	0	0			
16.	40	50	120	1440	15	0	0	160		
17.	40	50	120	1440	15	0	0			
19.	40	50	120	1440	15	0	0			
20.	60	50	130	1610	15	0	0			
21.	60	50	130	1610	15	0	0			
22.	70	50	140	1740	15	0	0			

It will be noticed from Chart I that the patient's initial diet contained twenty grams of carbohydrate, and one hundred grams of fat, and on this diet his urine became sugar free on the third day with the aid of nine units of iletin a day. The diet was then raised from 1,140 calories to 1,440 and the iletin to fifteen units a day. Five days later the diet could again be raised to 1,600 calories and again three days later to 1,700. In the meantime the blood sugar, G, had been reduced practically to normal. The subsequent history of this patient is that since he left the hospital he has continued to improve and his weight is now 122 pounds. His strength and sense of well being have increased even more than his weight might signify.

We have a number of patients of this type who, under ordinary circumstances, would not be able to carry on any occupation, but who are, with the aid of iletin, pursuing light occupations and making their living. It is not difficult to teach any patient to administer iletin to himself.

I have never seen a recovery from diabetic coma treated by the older methods. I have once or twice seen the patient brought back to consciousness for a matter of hours. Therefore, to me, recovery from diabetic coma to such an extent that the patient left the hospital in some semblance of health is indeed a dramatic incident.

CHART II.

	Diet				*Units*	*Urine*		*Blood*		
Oct.	*C*	*P*	*F*	*Cal.*	*Iletin*	*G* *Gram*	*K*	*G* *Mg.*	*CO*$_2$	
3.				?	70	++	+++	330	9.7	in coma
4.	50	43	50	700	100	++	+++	260		conscious
5.	50	43	50	700	70	25	++	288	37	
6.	50	43	50	700	40	19	++	304	40	
7.	50	43	50	700	100	61	++	248	44	
8.	50	43	50	700	80	44	+			
9.	50	43	50	700	60	7	+			
10.	30	40	60	820	60	4.4	0			
11.	30	40	60	820	60	0	0	150	55	

Chart II is the record of one of our cases of diabetic coma in which the patient recovered. He was brought to the hospital in deep coma and the severity of the acidosis was notable in the carbon dioxide combining power of the blood, 9.7. In just one week the urine was free of sugar and the blood sugar had been reduced to what might be called a fairly normal level with all evidences of acidosis gone. The diet in this case was subsequently raised considerably and the patient accordingly gained weight and strength and left the hospital in splendid condition.

We have had seven cases of recovery from diabetic coma.

Another field in which insulin has proved of greatest help is in the treatment of diabetes with surgical complications. One of the commonest instances that come to my observation is severe infection requiring surgical treatment in diabetic subjects. These cases present a serious surgical hazard. [The mortality under the older methods was over seventy-five per cent.] From the history, it may be judged in many cases that the diabetic state has been of long duration and is not severe. These patients are often stout, sometimes even obese. When an infection occurs there is at once a marked increase in the severity of the diabetes as a consequence of the infection. The fever becomes an added factor in speeding up metabolism. The result is a serious infection in a severe diabetic. The mortality in these cases has always been high. If the patients are not operated upon they are sure to die. If they are operated upon they probably will die. Ether increases the hyperglycemia, and likewise the acidosis. Several cases of this kind that we have had the opportunity to treat with insulin resulted so satisfactorily that I think it is safe to say that could one start with insulin before operation one could be reasonably sure that the patient would not die of diabetes. An astonishing fact concerning some of these cases is that when the infection has subsided, the diabetes not infrequently turns out to be quite mild and the patient does not any longer need insulin treatment, but can be maintained quite comfortably by the older methods.

It may well be asked what necessity is there of any restriction in diet if insulin is used in large amounts. The answer to that, it seems to me, is found in the fact that insulin cannot be used in large amounts unless the patient is constantly under observation or has been under observation a sufficient length of time to determine, with some exactness, the relation of the high dosage to a definite diet. Now, if this diet is transgressed, symptoms develop analogous to those in diabetics who have had no treatment, namely, thirst, polyuria, etc.

Then, too, when the insulin dosage is high the carbohydrate dosage, too, must be constant or there will in all probability be accidents. All observers have noted that a fairly constant and definite ratio between total carbohydrate in the diet and the number of units of insulin used seems to exist for each patient (2).

This ratio is individual and varies in different cases but for successful treatment it must first be determined, then adhered to, and occasionally corrected.

Antipituitary Serum

A Biological Treatment of Diabetes

By C. LEGIARDI-LAURA, M.D.,
New York.

All recent efforts point toward the finding of a biological treatment of diabetes mellitus. That is why I think it is unnecessary to discuss at length the advantages of a biological treatment, as compared with the dietetic treatment, which has been tried for over half a century, and under the light of present knowledge appears to be a purely empirical method of treating this disease. Considering the bad results of partial or temporary total starvation, as tried in Europe under the authority of Cantani and Guelpa, and more recently in America under the authority of Allen, it is only natural that workers should be looking in some other direction.

Notwithstanding an enormous quantity of work, the causes of diabetes mellitus are still very obscure. Nevertheless, there are several fundamental facts which we know, at least partially, and which offer some good material. Among these facts, the most prominent is the influence of the endocrine system on general metabolism. I must note here, briefly, that diabetes mellitus is not a disease of faulty sugar metabolism alone, but in this disease all the functions of general metabolism are always more or less disturbed, although of course the disturbance of sugar metabolism is the most apparent. Now, the studies of the last quarter of a century have proved that metabolism in general is under the control of the endocrine system.

As for the special metabolism of carbohydrates there are experiments which attribute to the pancreas the most important functions of control; other experiments give predominance to the pituitary body. The influence of the thyroid in this respect is not so well defined, and the adrenals, which have been supposed for a time to have a direct bearing on sugar metabolism, have been put aside, when it has been shown that their influence was only on the mobilization of sugar, not a true metabolic process. So the pancreas and the pituitary offer the best field of research. In this country the pancreatic theory of diabetes has the greater number of followers in the medical profession, undoubtedly on account of the authority of Allen. That the depancreatized dogs become diabetic is a fact which has been established by several observers. That the pancreas is the seat of alterations in human diabetes, has not been proved, and certainly it is not likely that a pancreatic disturbance is the general cause of diabetes in man. Such distinguished men as Lepine in France, and Massaglia in Italy, have pointed out the differences of experimental diabetes and the spontaneous disease in man. Lepine (1), in 1909, affirmed that *"Le diabète pancreatique n'a que rarement son analogue dans la pathologie humaine.*

On the other hand the work done both in this country and abroad on the influence of the pituitary on sugar metabolism are also interesting. But strange to note, while the pancreas has attracted so much attention by the clinician and the practitioner, the pituitary has been confined, as far as sugar metabolism is concerned, to the experimental laboratory. Working on the experimental researches of Vassale, Massaglia, De Bovis, and notably of Cushing and Goetsch which prove that hyperpituitarism and hypopituitarism are respectively the exponents of lowered or increased sugar metabolization, I have for several years tried to find a biological method of treatment. Briefly, I worked on the following hypothesis: That the main control of sugar metabolism is the posterior part of the pituitary, that an increased production of hormones from the posterior pituitary is directly or indirectly the cause of diabetes in certain classes of patients at least, and that it is possible to counteract this overproduction of hormone.

Antihormones were first produced by Ferdinand Blum of Frankfort, using adrenal extract as antigen, and by Charles Beebe using the thyroid. With this theory I tried to produce a serum antagonistic to the pituitary, by using extract of pituitary (posterior and infundibular) as antigen, and injecting this into the horse. I have published (2) a preliminary account of my results.

The first thing that I noted was that such serum injected in man determined a decrease in blood pressure in practically every subject. This depression occurred after small doses, which was indicative that it was not due to the normal proteins of horse serum, and it occurred also without any sign of anaphylaxis. To make this interesting fact certain, I have experimented with several subjects, using normal horse serum as a control. I have also compared the action of antipituitary serum when injected simultaneously with pituitary extract and the action of horse serum similarly used with pituitary extract. From the results obtained I have no doubt that the depressive action of antipituitary serum on blood pressure is specific, or it is due to substances which are not present in the normal horse serum. That is why I feel justified in calling this product antipituitary serum and in considering it as containing special bodies which are acting as antibodies in regard to the physiological extracts of the pituitary on blood pressure.

The following cases are examples of the comparative action of antipituitary and normal serums:

Case I.—G. T., a man of forty-five years whose blood pressure (systolic) taken in different days, about the same time every day, had been oscillating between 120 and 130 with only one day out of five in which it was only 110, without interference.

The first day the blood pressure was 125; then two c. c. of normal serum were injected subcutaneously and twenty minutes afterwards the blood pressure fell to 120, and returned to 125 ten minutes later. The next day the original blood pressure was 125; four c. c. of normal serum were injected; blood pressure was 120 fifteen minutes later; blood pressure was 125 and 120 fifteen and twenty minutes later. The third day the original pressure was 120 and the injection of four c. c. of normal serum did not give any action. Twenty minutes afterward the blood pressure was 125.

It seems evident from this that in this case the injections of from two c. c. to four c. c. of normal serum have no appreciable influence on the blood pressure.

On the same patient four days after the last experiment, pituitary extract (one c. c.) was injected and the blood pressure which was 110 before the injection went up to 138, twenty-five minutes after the injection. Three days afterward the normal pressure of 120 remained unchanged after the injection of one c. c. of pituitary extract together with an equal quantity of antipituitary serum.

Comparing these findings with the definite action of antipituitary serum as it appears from the cases that I have referred to in my previous note, the difference is striking. In every case the blood pressure went down progressively, beginning about twenty minutes after the injection, and remained down twenty to thirty points and sometimes more, for several hours, or in some cases for days.

Indeed, in one case reported previously, of a patient suffering from arteriosclerosis, the arterial depression produced by this serum remained for several days.

Lately I had the opportunity of seeing another similar case which I report briefly:

Case II.—A woman of fifty years, affected by hypertension from arteriosclerosis, seen January 27, 1922. The blood pressure was originally 200. It fell to 175, twenty-five minutes after an injection of two c. c. of antipituitary serum. On January 28, 1922, the blood pressure was still as low as 170, and fell to 160, twenty-three minutes after injection of two c. c. of antipituitary serum. On February 1st the blood pressure was again 190 and went down to 170 twenty minutes after the injection.

Another case of high pressure is that of a man sixty years old, suffering from hemiparesis as a consequence of arteriosclerosis. His blood pressure went down from 190 to 160 after one c. c. and the next day it was only 170 before the injection and 135 after two c. c. had been injected.

Whether this fact can be utilized as a means of treatment for hypertension it is not yet clear to me although it might be useful in order to obtain a rapid decrease of blood pressure when this is high enough to threaten the life of the patient.

I have referred to this action of the serum essentially in regard to its physiological significance as it proves that the serum obtained from the horse, after immunization with the posterior pituitary, has antagonistic properties to the extracts of posterior pituitary. In other words, it proves that it is possible to produce a serum which contains substances antagonistic to a hormone property.

My experimental work on diabetic patients covers a period of about six years and includes at present fifty-two cases. Practically all were of long standing; none of the patients had been ill for less than one year; many for several years. Most of them had consulted several physicians, and had gone through the useless torture of dieting. Several of them have been recommended to me by colleagues who were getting tired of their cases, or were discouraged by the negative results of the diet treatment, or were willing to see the effect of an experiment of biological treatment. All the cases except three were uncomplicated. I was careful in excluding cases complicated with renal disease, especially at the beginning of the experiments, when I used large doses of the serum (five c. c. or more).

In my first cases I tested the sugar tolerance of the patients by first getting them free from glycosuria, and then allowing them a progressively increasing amount of carbohydrates *pro die* until sugar reappeared in the urine. Then I administered the serum and noted the result on the amount of sugar in the urine. If the result was favorable and glycosuria disappeared I allowed a larger amount of carbohydrate progressively until the new limit of tolerance was reached; then I gave another injection of serum, and so on. My first experiments, as published in 1919 (2) gave me a remarkable proportion of favorable cases—about fifty per cent.

At that time I considered as favorable only those cases which showed a complete disappearance of glycosuria with a full uncontrolled diet. As I became more familiar with the method I realized: First, that large doses of serum were not necessary. Second, that cases that do not respond to the first five or six injections would not respond at all. Third, that the percentage of favorable cases is higher than fifty per cent. if well conducted. Fourth, that it is unnecessary to starve the patient in order to get him free from glycosuria before trying the serum therapy.

Meanwhile the cases treated in the first series (and I must refer the reader to the paper) proved that antipituitary serum really increased sugar tolerance in a considerable number of patients. These first cases also showed me that not only glycosuria and hyperglycemia and polyuria are reduced by the serum, but that also the general condition of the patients, as well as special symptoms—trouble of vision, loss of weight, neuralgic and neuritic pains, cephalea, pruritus and other conditions were ameliorated or cured.

Let us emphasize this point: We do not cure a patient of diabetes, unless we restore to him—at least in part—the capacity of using carbohydrates. We certainly do not cure him by simply getting his urine sugar free, and his blood free from excess of sugar, if we obtain this result at the expense of his nutrition. What we purpose is to restore to him a certain capacity of metabolizing sugar and using it for the production of heat and energy.

In my first series of cases, out of thirty patients treated fourteen had such increased tolerance for carbohydrates, under the serum treatment, that the glycosuria disappeared, notwithstanding the fact that the intake of carbohydrates was notably increased. All fourteen patients were able after the treatment to tolerate about one hundred grams a day of carbohydrates, which accounts for the improvement in their general condition. Some of them could be put on free uncontrolled diet and still be free from glycosuria months after the serum treatment had been discontinued. Successive observations have shown me that some patients show occasionally a reappearance of glycosuria sometimes after a few weeks, sometimes months after the discontinuance of the treatment. When such is the case the administration of the serum for a few days makes the glycosuria disappear again.

I report here four cases which give a clear idea of what we can really accomplish by this method. One was reported in my preliminary note, and it is interesting to know what the conditions are now, two years after the last treatment.

Case III.—(Case IV of my preliminary note). G. D., a man, aged forty-six, who had suffered from articular rheumatism since his infancy and had been declared unfit for the army in Italy on account of heart trouble. His diabetic condition was discovered about three years before my first examination, which took place on March 9, 1918. His symptoms had been progressive weakness, sexual impotency, diminution of weight, almost constant headaches, and a sciatic pain which compelled him to stop working for periods of several months at a time. About a year before I examined him, he had been obliged to give up his position entirely. At the time of my examination, the patient was emaciated and very weak; the urine contained 5.10 per cent. of sugar, and the blood contained 0.46 per cent. His sugar tolerance was found to be less than thirty grams, while a diet free from carbohydrate, brought acetone and diacetic in the urine. The first injection of the serum made the urine sugar free. Then one hundred grams of white bread were added to his food for three days and five c. c. of serum were injected. Sugar in urine was 0.80 per cent. the next day. With the same diet five c. c. serum were administered and the urine was found sugar free two days after. The patient was then gradually brought to a diet containing about two hundred grams of bread a day, with no limitation of other food, while serum was injected every five to seven days until about the end of July, when the patient was found free from glycosuria and the blood sugar had decreased from 0.46 per cent. to 0.26 per cent. Meanwhile, the sciatic pain completely disappeared, the body weight increased, and general conditions were so good that on September 2, 1918, six months after the beginning of the treatment, the patient was able to reassume his occupation in a factory. According to information obtained at the date of this article, the patient is still feeling and doing well.

Case IV.—Mr. G. H., aged fifty-five years, seen by me the first time in July, 1922. Mother and eight brothers or sisters were all subject to chronic rheumatism. Fifteen years ago he had had pruritus lasting from three to four years, and was cured by dieting. He did not exclude starch and could not tell if he had at that time sugar in the urine. Two years ago he began to suffer with bad sciatic pains in the left leg. The urine was examined last November and found to contain 2.50 per cent. sugar.

The patient was placed on a diet free from starchy food, and the glycosuria disappeared, but he was feeling "miserable" as he stated, and upon partaking of farinaceous food again, sugar reappeared in urine at the rate of four per cent. The patient restricted his diet again and the urine sugar decreased, but the general condition of the patient became poor. He had not consulted a physician since last March, and on his own judgment increased the intake of carbohydrates. The general subjective condition of the patient became much better, but the sugar reappeared in the urine.

At the time of my first examination (July 26, 1922) the urine contained one per cent. sugar; no acetone or diacetic acid; faint traces of albumin. Patient appeared to be about sixty years old, was prematurely bald, and poorly nourished. On July 30th the first injection of antipituitary serum (one c. c.) was given. On August 3rd the urine contained 0.1 per cent. sugar; no acetone or diacetic acid; urea, 1.0 per cent. notwithstanding the increase of carbohydrate intake of about a hundred grams of white bread a day and thirty grams of oatmeal with milk every morning. This patient's urine was sugar free after the second injection; the intake of carbohydrates was increased every week, while the injections of two c. c. of serum were repeated twice a week. The patient was on full uncontrolled diet, had had six injections of serum in all; he was free of sugar, felt perfectly well, and the sciatica had disappeared.

Case V.—Mr. Z. G., sixty-three years old. Nothing was known about his family history. Sugar in the urine was first discovered six months previously, when he went to consult a doctor on account of an annoying frequency of urination. The sugar in urine was found to be five per cent. I saw the patient for the first time on March 26, 1922, after he had been kept for about five months on a diet free from farinaceous food, without relief from the frequent urination. On March 26, 1922, the blood pressure was 120-100. The liver was moderately enlarged. The general condition was apparently good. After a week of diet poor in proteins, and with complete exclusion of farinaceous food, the glycosuria was reduced to three per cent. On April 11th the urine still contained three per cent. sugar. The first injection of serum was administered (two c. c.) and repeated at the same dose three days afterwards. The next examination of urine showed one per cent. sugar. On April 23rd two c. c. serum was given. The urine examined on the 25th contained 0.5 per cent. sugar, no diacetic acid, no albumin. The diet was then increased with about one hundred grams of farinaceous food a day. The urine was sugar free on the 28th of April, with patient feeling well and normal frequency of urination. He had a reappearance of glycosuria on one occasion during September, which disappeared after one injection of serum. This case was not concluded although the patient felt well up to this date.

Case VI.—Mr. G. R., aged forty-eight. Diabetes was first recognized toward the end of 1914, when the sugar in the urine was above two per cent. on a mixed diet. He consulted several physicians and submitted to a starch free diet several times, but the urine never became free from sugar. The patient was recommended to me by a colleague about March, 1921. His urine was found to contain from one to 2.8 per cent. on different days on a diet free from starch. During a period of about a month, the patient had six injections of serum (two c. c. each) and the urine became sugar free.

Then the patient discontinued the treatment; he had his urine examined several times in 1921 when it was usually found free of sugar, with an occasional trace present. Patient continued on a full uncontrolled diet. Sugar reappeared in the urine about eighteen months after the patient had discontinued the treatment, glycosuria being a little above one per cent. On August 2, 1922, I administered two c. c. of serum and two days afterward the sugar in the urine was reduced to traces. The second injection was then administered and the urine became sugar free. The patient had five injections of serum up to September 20th; sugar did not reappear to the present time, although the patient had taken every kind of food *ad libitum.*

I have never noted anaphylactic shock in any of the patients. At the beginning of the experiments when I used large doses of serum, I had three or four cases of serum sickness, manifested by a rash. Later on, using only from one to two c. c. of serum, I did not notice any notable inconvenience. Of course it is prudent in using any serum in which the proteins have not been reduced in amount, first to sensitize the patient with a few drops of serum, following in an hour with the rest of the dose, also to have a one per cent. solution of adrenalin at hand to be given hypodermically if needed. With this precaution the administration of the serum is safe. Cases with serious renal complications should not be treated with the serum, unless with great care. I have never administered the serum in cases of diabetic coma.

CONCLUSIONS.

1. By treating the horse with parenteral administration of extract of posterior (infundibular) pituitary, we can obtain from the horse a serum which shows, by its effects on the blood pressure in man, to have properties antagonistic to the physiological action of pituitary extract.

2. This serum applied to the treatment of diabetic patients increases the sugar tolerance in from fifty to sixty per cent. of the patients as shown by disappearance of glycosuria with increased intake of carbohydrates. This increase in sugar tolerance in the mentioned cases is sufficiently high to give to the serum a true therapeutic value, as it enables the patient to metabolize a quantity of carbohydrate food (from a hundred grams to three hundred grams a day or more) which is sufficient to prevent acidosis, and restore the general wellbeing of the patients.

3. Of the cases of diabetes which have been treated successfully with this serum, some patients have been kept well without dietetic limitations; others are still in need of a certain limitation in the intake of carbohydrates; but none of them need to go to the extremes of complete withdrawal from food. As for the patients who did not respond to this treatment, I am positive that they did not respond to starvation treatment, i. e., that their sugar tolerance has not been permanently increased by periodically repeated starvation treatment.

The Mental Concomitants of Diabetes Mellitus*

By CLEMENT B. MASSON, M.D.,
Washington, D.C.

Although the relationship between physical and mental phenomena is conceded to be a close one, a wide gap still appears to exist in our actual understanding of the phenomena present, largely because internists and psychiatrists have not as yet developed the singleness of viewpoint which would enable one to interpret the mental in terms of the physical. More specifically we are concerned here with the type of phenomena observed in the course of disturbed carbohydrate metabolism and the mental reaction accompanying the same.

It has long been observed by others and more particularly by Halberstadt and Arsimoles that there is much confusion caused by classing all persons who are insane and have sugar in the urine as subjects of diabetic insanity. Leaving aside such elementary mental disturbances as change of character, and others which have been attributed to diabetes, and directing attention to insanity proper, there are three groups of facts which deserve attention.

First, those cases in which diabetes is only a complication or passive accompaniment of an attack of insanity. Cases of autotoxic origin and admittedly due to diabetes. And lastly, those instances in which diabetes exists and through arteriosclerosis causes cerebral deterioration.

The form of insanity is usually depression with morbid fears for the future, delusions of worthlessness, while hallucinations are not uncommon.

W. R. Rawson distinguishes two classes, one in which morbid mental phenomena have arisen in the course of glycosuria, the other in which glycosuria developed during an attack of mental disease; the former class being rare, the latter fairly common. It is to be noted how frequently authors mention melancholia as an associated mental state with diabetes mellitus. Dr. C. H. Bond states that in patients with insanity diabetes frequently develops; patients with diabetes are rarely noted to manifest a psychosis; patients with melancholia were especially subject to this complication.

Allen states that actual diabetic psychoses, i. e., psychoses which can be attributed to the diabetes as the cause, are rare. In view of the frequency with which diabetes develops on the soil of a neuropathic diathesis, the statistical conclusions that 1.2 to 1.7 per cent. of diabetic patients become affected with psychoses loses much of its value as to a direct causal relation of the diabetes to the psychosis. With an increasing quantity of sugar in the urine, frequently psychic, nervous symptoms of a general nervous nature and mostly of a neurasthenic character are observed; irritability, flaccidity, feeling of physical weakness, of lessened capacity for work, headaches, head pressure, hypochondriacal complaints. The mental disorder which is associated with diabetes is usually of a mild depressive type often with ideas of ruin and sin. Anxiety states have also been described. In general the severity of the mental symptoms may alternate with the severity of the physical disease, as indicated by the sugar eliminated. When the intoxication is great the patient may be irritable, sleepy, stupid, complain of weakness and headache.

In some subjects of diabetes, states *Le Practicien*, certain changes in the normal nature are so marked as to point to a correct diagnosis before an examination of the urine has been made. A young man, who in consequence of this disease has lost his virile power, will state the fact of his impotence to his physician with a sort of indifference, extremely different from the anxious fear displayed by the hypochondriac under like circumstances. At a more advanced stage of the disease, when the quantity of sugar in the urine is considerably augmented, the mental state changes. The patient becomes sad and is the prey of hypochondriacal forebodings. His character changes; from being free and open hearted he becomes morose and moody, speaks but little and smiles less. He becomes parsimonious and tries to cut down the expenses of his household, begins to keep exact accounts, calculates his resources and declares that he is ruined and that his family will die in the poorhouse.

The man of middle age, who, without apparent cause and without exhibiting any other mental disturbance, becomes all at once avaricious and presents delusions of rapidly approaching final ruin, is frequently a diabetic. If these melancholic forebodings continue, and if on examination the presence of sugar in the urine is established, the chances are that the patient will end his life by suicide. In the later stages, after the disease has existed for some length of time, still another mental condition is noted. The patient is lazy and wants only to be alone, he will spend hours in a state of complete mental and bodily inactivity; his mind is clear, and his intelligence is unimpaired, but he is apathetic. He has no desire to walk or talk, and seeks no occupation. Later, while preserving all his mental faculties intact, he begins to indulge in soliloquy and relates incidents and recalls old memories to himself in an undertone. Finally, he falls into a state bordering on marasmus, and is carried off usually by that most grave of the complications of diabetes—pulmonary tuberculosis.

Savage states that in insanity proper, diabetes is uncommon; diabetes and insanity run together in the same families. When diabetes and insanity coincide, the insanity is generally of the melancholic type, and the symptoms are modified by the relationship. Also quoting Maudsley (*Pathology of Mind*)—nearly all patients with diabetes with insanity were melancholic.

In one of the reports of the Medical Society of London it is stated that many psychiatrists admit of glycosuria appearing at the time of depression and disappearing with physical improvement. While their observations are of interest I do not consider their cases the same as such cases of glycosuria that sufficient attendant symptoms make the diagnosis of diabetes mellitus positive.

---

*From the Acute Medical Service, Saint Elizabeth's Hospital, Washington, D. C.

An interesting tabulation of 175 cases examined within forty-eight hours of admission showed that, excepting general paresis, all the other psychoses, and three cases of diabetes, while under melancholia, six cases of diabetes were listed. In two melancholics who recovered, the improvement of their mental condition was coincident with the gradual disappearance of glycosuria.

A. Parot states that his patient had recurring attacks of melancholia which were always accompanied by a marked glycosuria. The attack under observation had as its apparent initiative a violent attack of anger. The author emphasizes the psychophysical parallelism, but unfortunately from lack of knowledge of the technic of study of the unconscious by psychoanalysis, does not develop all that might be gained. A series of cases of depression alternating with glycosuria are known, which, had the author the facts from the psychoanalytical technic to guide him would have made this extremely important problem of liver function and its mental integration clearer.

How many of the cases referred to above which are not at the involutional period, not arteriosclerotic, and not tainted with a psychopathic background, the writer has not determined, but certainly it should be considered.

Horace Victor Pike states that it is not uncommon to find patients suffering from various types of psychosis who present the clinical and laboratory evidence of diabetes mellitus, in which the glycosuria appears solely as a complication of the mental disorder. These psychoses should not be confused, however, with that more uncommon group in which the mental manifestations are unquestionably due to an autotoxemia resulting from a faulty sugar metabolism in which the psychic symptoms are typical and fairly constant.

The one case reported as being psychosis induced by diabetes mellitus is in a man aged fifty-six in which the arteriosclerotic condition must not be overlooked. From the case report diabetes mellitus might be conceded to be the cause of the psychosis. I should like to see a case in which the patient was not at the involutional period or in a senile state, where the somatic condition could be said to be the cause of the psychosis.

Quite similar observations are reported by H. Singer and S. N. Clark, who state that the type of reaction common to brain intoxications of all kinds is hallucinosis, which may or may not be associated with clouding of consciousness. The manner in which the patient reacts to sense falsifications depends upon the individual's habit of reaction. In diabetes there is more or less severe disturbance of general metabolism, which, in some cases, causes toxic brain disturbance. These cases are rare in the author's experience. The periods of acute toxic symptoms coincide with diminution of the amount of sugar in the urine. In the first case production in the amount of sugar in the urine occurred with appearance of albumin and casts, showing parenchymatous change in the kidney. In the second case the reduced sugar was noted only in connection with therapeutic efforts.

CASE I.—White woman, aged about thirty-seven, mental age eight and a half years. Previous health, up to three years ago was fairly good, showing no signs of mental disturbance. Then she began to hear voices, and became frightened; was sent to the psychopathic hospital. Diagnosis here was toxic hallucinosis, probably alcoholic. She then was sent to the insane asylum, coming under my observation. She was quiet, but mildly fearful. Bodily organs showed presence of glucose, no albumin nor casts; Wassermann reaction was negative, both in blood and spinal fluid. She weighed 135 pounds, was well nourished, and no sign of other disease was detected. After a few days apprehension disappeared, and she became a quiet, steady worker. During the next six months sugar was constantly present in from two to four per cent., but there was no further mental disturbances. Although no rigid diet was ordered, the sugar became lessened (one or two per cent.) and she was apparently well. She was allowed to return to Chicago in the care of the Mental Hygiene Society. All the symptoms returned after the first day and she was returned to the asylum. After this she became quieter, although still apprehensive, and showing signs of hallucinations. Examination of the urine showed at first two per cent. of sugar which became less and then albuminuria with hyaline and granular casts appeared. The patient's mental disturbance subsided somewhat. The amount of sugar in the urine also fluctuated. At no time was there an excess of acetone in the urine, nor was any diacetic acid found. The blood alkalinity was not estimated. As the sugar decreased in the urine, the mental state became worse.

CASE II.—White woman, aged forty-seven. Her father had been a hard drinker and manifested mental disorder at the age of fifty-eight, which persisted until his death at sixty-four; mother died at seventy, but was childish since the age of sixty-six. She had had occasional headaches, attack of chorea at age of six, which lasted one year. Married at age of thirty-two; two miscarriages; menopause at thirty-nine years. She was flighty, cranky, easily angered, and quarrelsome; some excess in alcohol. The mental disorder began six years before, abruptly; heard voices, threatening, also had uncomfortable sensations, with finally fixed hallucinations of persecution. Soon after this she was admitted to the asylum under my observation. Examination showed the patient to be quite obese, complaining of vertigo and flushing of the face. Neurological examination showed a slight Romberg's sign, with diminished kneejerk; tremor of fingers, tongue and eyelids. Her memory, recent and remote, was good; she talked freely of persecution and sensory disturbances. During the following five years, there were periods of quiescence and exacerbation. Once it was possible to send her home.

Uranalysis showed 69.75 grams of glucose in a twenty-four hour specimen, with dermatitis of perineum and thighs. Within the last two years this amount had been increased to as much as 318.09 grams in twenty-four hours. Thirst and appetite were not excessive. Restricted carbohydrate diet, lessened the sugar to between fifty and a hundred grams daily. Patient said spirits bothered her less at night after restricted diet; mental picture unchanged.

Increase in amount of sugar showed no change in attitude. On a strict Allen diet the sugar in the urine dropped from 202 grams in twenty-four hours to 8.75 grams. This decrease brought more marked complaints of sensory disturbance and hallucinations. Her expression changed to one of acute distress. Added carbohydrates brought a slight rise in the sugar content of the urine, and caused the patient to improve rapidly, so that she became quite good-natured and quiet in behavior. This was again tested later, with the result that her distress increased as the sugar decreased in amount, on full diet returning to a state of average comfort.

In fact from their report in one case at least the patient's mental symptoms seemed to be held in abeyance somewhat when fed such food that sugar was present in the urine in large amounts.

It is interesting to try and explain, why with sugar in the urine, an abnormal constitutent bespeaking disturbed metabolism, a patient should not show any change in mental status as near as I could observe, and it is still more interesting to try and explain why a patient's mental health so far as symptoms capable of being observed are concerned is better having a greatly disturbed metabolism than when this is reduced by dietetic treatment.

In contradistinction to our first class of cases of diabetes and insanity we have in the following a report of a case of diabetes in which a psychosis of short duration might be called a complication of the somatic disease.

Klieneberger reports a case of symptomatic episodic psychosis in a diabetic patient. Bonhoeffer says that psychoses based upon diabetes are rare.

CASE III.—The patient was fifty-six years old, and had been a diabetic for twelve years. He had a carbuncle which was cut, and subsequently he was admitted to the hospital. A psychosis then developed which was varying in type, and disappeared spontaneously after a few weeks. In the foreground of the symptoms were illusions pertaining to his state, thinking he was in heaven, or dead, and that he heard God's voice. There was furthermore catatonic motor irritability, with pathetic, ecstatic conditions, such as are seen in epileptics. He would constantly sing loudly, and monotonously. Stereotypy, verbigeration, incoherent rhyming, were some of the symptoms. When motor irritability set in the patient was unapproachable, lost his orientation. When these motor conditions wore off one could converse with the man. He would then try to explain his previous conduct, and give fairly good answers about his symptoms. He was in good humor throughout his psychosis, which died away gradually within six weeks. He later took up his work and was not much worried about his previous mental condition.

The paranoia existed separately, and was of a religious type. He was, and always had been, a religously inclined man, and knew the purport of his diabetic condition. He had a friend who died of diabetes, when he was admitted a third time to a hospital and who was on his mind a great deal. I see a natural connection between his symptoms during the psychotic state in the hospital and his disposition before entering the hospital. He had been worried about the carbuncle, which did not heal readily. He was afraid of dying. The exogenous psychosis created a dulling of consciousness as in the sense of a prepsychotic disposition. As soon as consciousness became clear again the hallucinations and illusions disappeared. The patient's mother had had a manic temperament, his sister was psychopathic, and committed suicide. The patient was of a manic disposition, but did not present the depression during his attack. In this case the patient had an altered metabolism over a period of twelve years, but during all this time was not psychotic.

There are, as in cancer, ulcer of the stomach, and pulmonary tuberculosis mental troubles dependent upon the organic condition, exogenic psychic disturbances. So in diabetes aside from a definite psychosis we may have less organized and less malignant mental troubles.

G. Aymes states that for some time two kinds of psychic troubles have been differentiated in diabetics. 1. Elementary mental troubles, consisting particularly of change in disposition and habitual manner of living. Disturbances of the intelligence are quite rare in diabetics. Even in diabetics in whom the changes of disposition constitute veritable elementary mental troubles, the perception of analogies, of relation between ideas, the possibility of clear and distinct concepts remains intact.

Even when they say they are ruined, lament, become avaricious in spite of their profound sadness, in spite of their rapid loss of weight, their pallor, they can still disguise their anxieties in public, attend to business affairs and appear to be quite as rational as they always were. What sometimes indicates the intellectual weakening is the difficulty which they experience in recalling the terms between which they were to judge. There can be an apparent weakness of reasoning in diabetics, when there is no real decadence of their intellectuality. Lasegne has called this "the loss of appetite for thought." The memory is most frequently touched. The troubles of memory are due rather to the fugacity and to the lack of emotional tonality of the impressions (which leave little or no trace—on the mirror consciousness) than to the difficulty of volition for the recognition and localization of these impressions. It is especially in the domain of sensibility that important modifications occur, perhaps complained of more frequently in the woman than in the man.

Frequently the diabetic presents an abnormal passivity, indifference, and hypoaffectivity for the family, which is sometimes increased by a hyperaffectivity for himself. This tendency of diabetics to become much worried about themselves, almost inaccessible to the preoccupations of others, to become avaricious, to believe themselves ruined, has been observed in a large number of patients. This indifference may be replaced or may even be accompanied by a sort of nervous erethism which shows itself through the mobility of disposition, alternative hypothermic and hyperthermic conditions. The former obtains especially in the morning in the hours which immediately precede or following rising, after meals, and after a prolonged muscular effort; the second is manifested during the occupations of the day, in family and social life, and may be different in expression; sometimes for an unimportant reason, the diabetic will exhibit a veritable transport of irascibility, during which even those dearest will be subjected to angry insults; sometimes they will show an abnormal expansive gaiety, with the tendency to be excited by their own conversation. There is in a diabetic the classical tendency to hypochondria, taking a form of analytical nosophobia, which urges the patient to discourse on the subject of his malady to the exclusion of every other subject. This hypochondria bears a direct ratio to the amount of sugar excreted. Sometimes the fear of death is mentioned —I have noticed this in two of my cases.

The erotic ideas which are frequently present in diabetic women have their origin in a pruriginous excitation, located in the genital organs, the clitoris, particularly the urethra. The consequences of this pruritus may be distressing excitation of the genitals, which leads these unfortunate women to solitary onanism. They succumb scandalized, despising themselves and hating their weakness. They may be brought, by veritable erotic impulses, to reprehensible acts, public outrages to modesty, the medicolegal importance of which can be seen. But this pruritus is never sufficient in itself to provoke real mental troubles or ideas of suicide. This secondary genetic excitation may be implicated in the impotence of certain other diabetics, who have lost all of their appetites, especially sexual desire. The existence of these modifications of sensibility necessarily bring about perturbations of the voluntary order even to the point that it is difficult to separate them clearly, and impossible to conceive of one without the others. Contour writes, "Diabetics become lazy, everything is tiresome for them, they recoil before the slightest intellectual or physical effort." My observations have confirmed the reality of these troubles; qualified to accomplish the daily round of an accustomed profession, the diabetic revolts at any change, at any attempt to orient his activity in another direction. Particularly is his power of sociability affected because he cannot restrain himself with the relative rigor of the world's conventions which require a high degree of attention, observation and mastery of one's self. From this cause springs the marked tendency to isolation which is observed in certain patients. There is a tendency to sleep in most of the patients—with insomnia in some. The latter can probably be explained by the frequent need of urination, which seems to cause a certain degree of cerebral excitation. In a few rare cases there is soliloquy. The author found in one patient aged seventy-two, a sort of automatism of speech without thought, which might more easily fall under the heading of intellectual deficiency. Six cases are reported in detail. The troubles manifested in these patients consisted especially of intellectual laziness and diminution of memory; of hypochondriac preoccupations; of changeability of temper, of emotivity, hypoaffectivity with

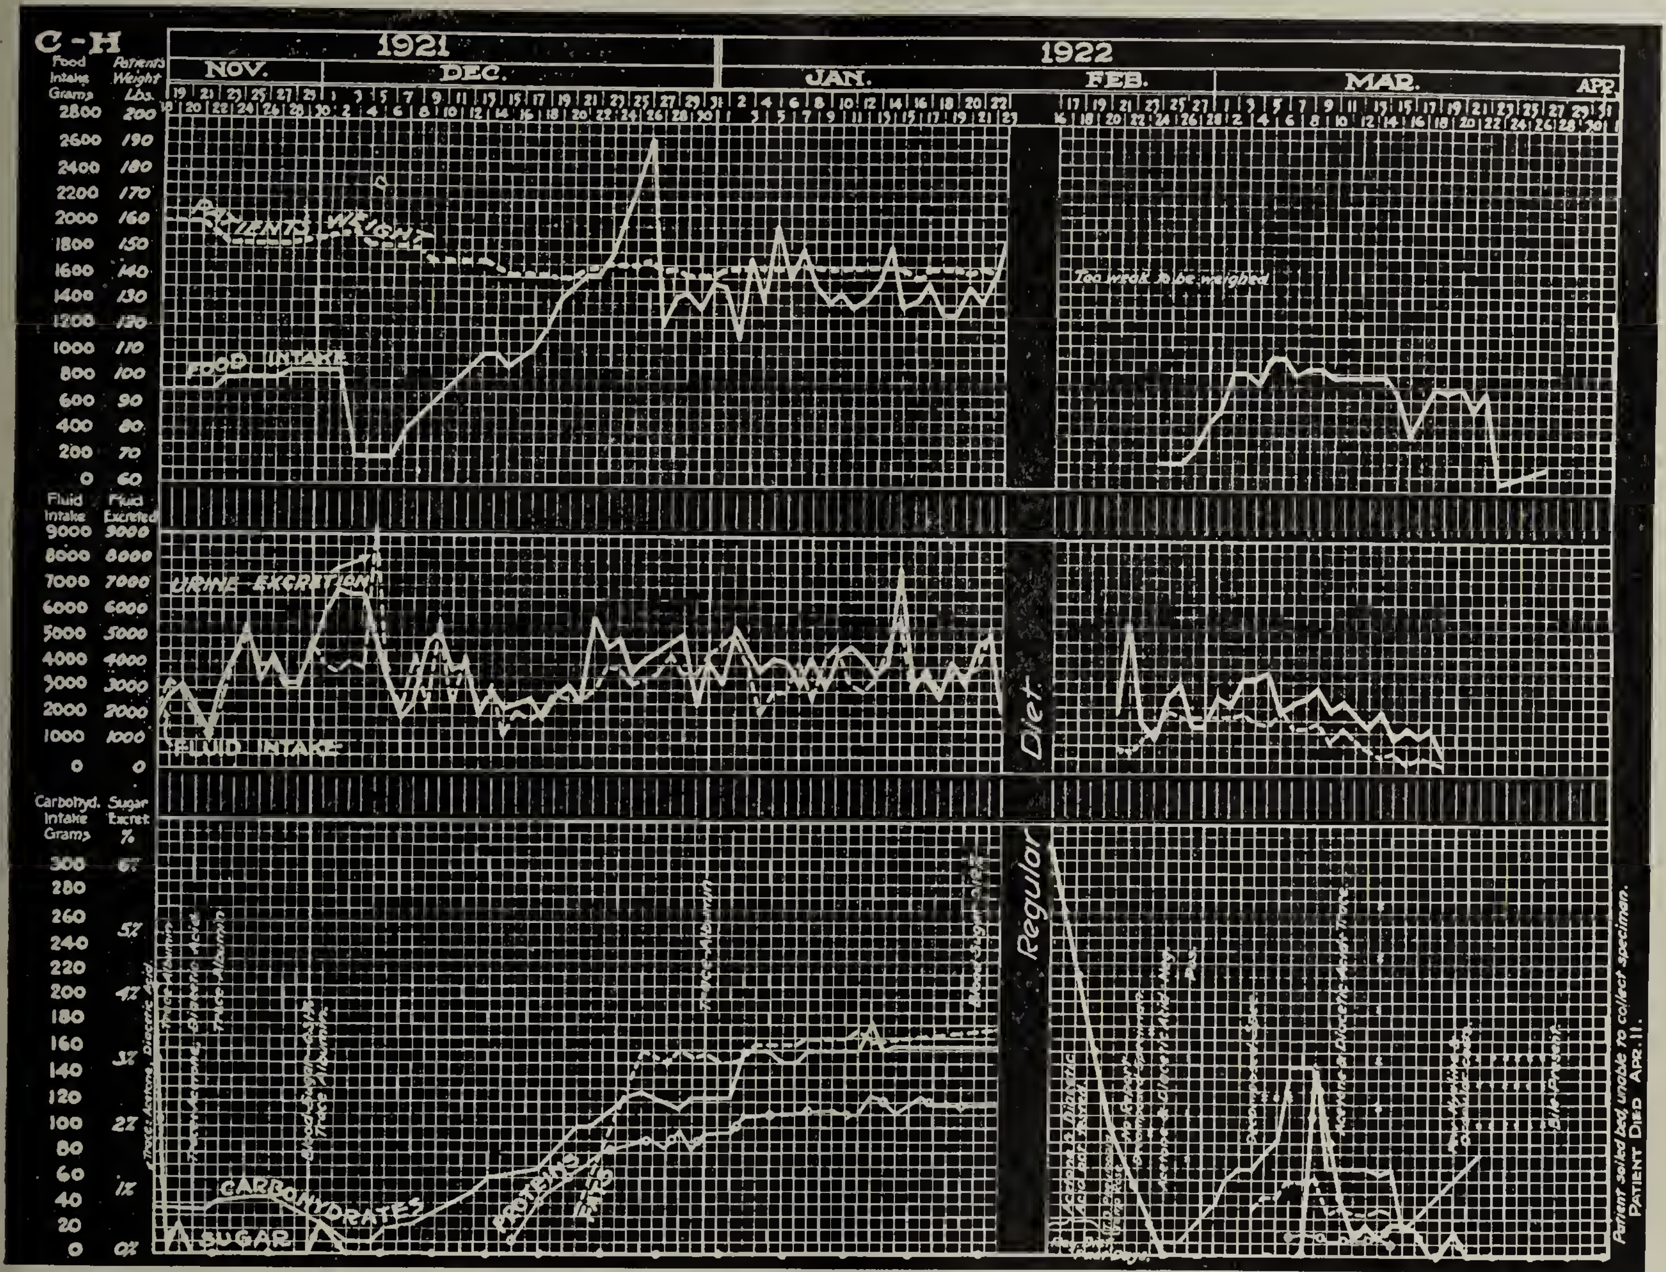

CHART I.—Showing amount of urine excreted, amount of fluid intake, carbohydrate, protein, and fats, in Case III.

egocentric tendencies, and diminution of moral and physical energies. In all the cases, special treatment was followed by variable results.

Mental troubles which are organized into veritable psychoses are rarer than elementary psychic troubles in diabetes. Insanity may exist before the diabetes; or the diabetes may exist before the insanity. In Bond's research, based on the examination of the urine of about fifteen hundred insane patients, is shown the rarity of transitory glycosuria. The only permanent glycosurias entering into the diabetic syndrome were mentioned by the family or revealed by the systematic analysis of the urine on entrance; just about six or seven in three years where there is a yearly registration of about three hundred patients. I made six observations on the relation of diabetes to mental troubles; in some, one can see the vesanic heredity, in others, this does not exist. In observation VII, the first of this group, there was no heredity; equally intense troubles accompanied glycosuria varying between 92 gr. and 64 gr. per 1,000 c. c. The antidiabetic treatment did not change the mental condition in the least. And even when this latter was improved and the patient was on a special diet, there were sixty grams of glucose to the litre in the urine. On her second admission, she had at the height of her anxious state twenty-one grams of glucose to the litre. When improved she had twenty-six grams.

Given the slight anteriority of diabetes in relation to the psychosis, these two morbid manifestations might be attributed to a general trouble of nutrition, making them simply concomitant. In observation VIII, there is the same nonparallelism, no heredity. In this case great importance must be attached to the neuropathic condition (undeniable hysterical stigmata) excellent terrain for the blossoming and development of these mental troubles. In observation IX, there was no heredity; the psychosis appeared slightly before the disappearance of the diabetic affection, and seemed to be substituted for it. These two successive disease manifestations interpreted an initial profound nutritional disturbance. Improvement during April under treatment was noted in observation X, and then nothing further. At certain times the amount of glycosuria diminished under the influence of treatment which is not at all correlative with the improvement of psychic symptoms. In observation XII there was a marked heredity; no relation between the amount of the glucose and the intensity of the mental troubles. The essential cause of the psychosis seems to be: sometimes a general disturbance of nutrition, provoking simultaneously diabetes and insanity, sometimes more or less marked hereditary predispositions, or a personal predisposition due to a manifest neuropathic condition. Cardiovascular troubles themselves certainly play an important rôle.

Of the cases that came under my personal observation the following are reported herewith:

Case III.—C. H., colored, indigent, admitted July 3, 1890, twenty-five years of age and diagnosed as chronic melancholia. The patient did not converse intelligently, seemed to comprehend some few spoken words, took no notice of his surroundings, always sat with his head drawn down. His habits were cleanly. In 1902 began working in the boiler room, continued in same condition mentally.

February 28, 1913, Dr. Dixon stated: "Patient was mute, refusing to talk either to patients on ward or answer questions. Took no interest in his surroundings and was very filthy in habits and untidy in appearance. Was very disagreeable with other patients at times. Memory was poor for recent events, fairly good for remote events. Worked at the powerhouse every day, where he rendered good service, but had to be watched to keep him from striking other patients occasionally."

Physical examination at this time revealed a large statured colored male. No evidence of any head injury. Respiratory and circulatory systems negative. The pupils were equal, round and regular. Reacted to light direct and consensual. Vaccinated February 8, 1913, against smallpox. The blood Wassermann was negative, August 5, 1915.

Up to the time of admission to the acute medical service the patient's physical condition remained good. A review of the chronic notes up to 1920 revealed that the patient remained essentially the same—stupid, quiet, working daily.

In presenting this case it may be well to give the manner in which a diagnosis was made. The patient was transferred to the acute medical service September 17, 1920 for cellulitis of the left hand with palmar abscess. To be brief, osteomyelitis of the distal phalanx of the thumb was found by x ray and the left thumb amputated by Doctor Sullivan on November 8, 1920. After an uneventful recovery the patient showed proficiency in polishing floors, hence remained in the hospital building.

Having no complaint and working about the ward quite content, little attention was paid him until it was noticed that he masturbated quite frequently and also drank large quantities of water. Upon examination the patient was found to have an elongated prepuce with a profuse mucopurulent discharge. This was negative for gonococci. Uranalysis showed sugar to be present.

To begin with the case proper: We have a tall heavy set colored man weighing 160 pounds. Appeared rather undernourished. Physical examination negative. On November 17th a twenty-four hour specimen of urine of 168 oz. or 5040 c. c. contained 4.2 per cent. sugar, specific gravity, 1.038. Otherwise the urine was negative.

The patient was placed on a vegetable diet and medication of urotropin and sodium acid phosphate and from October 21st to November 18th such treatment continued with variable results. Sugar was absent from the urine for so long a period as four days, then albumin would appear; occasionally both would appear.

On November 17th a trace of acetone and diacetic acid appeared in the urine. It was then decided to attempt entirely dietary measures, hence the Allen treatment after a fast of seventy-two hours during which time only water was given. While using a modified Allen treatment a daily chart was kept as to amount of fluid intake, amount of urine excreted, weight in grams of carbohydrate taken and the weight of the patient in pounds.

At variance with the rules of the Allen treatment seven hundred grams and five per cent. carbohydrate food per twenty-four hours was fed for five days, then eight hundred grams for six days. Upon the last day forty-five grams of protein was also added. For this twelve day period, November 18th to 29th inclusive, sugar appeared twice and albumin twice on different days, acetone and diacetic acid once. In eleven days the patient dropped in weight from 160 pounds to 153½. Results were discouraging; hence an attempt at the Allen treatment was decided upon, the reason for not adhering to it strictly being governed by the mental state of the patient from whom we could expect little cooperation.

Let us pause to consider the patient's mental symptoms from the time sugar was found daily in the urine to the present time. He remained rather mute, uttering few intelligible words; did not care to answer questions but worked constantly polishing the floors. He was untidy, masturbated frequently as he had been in the habit of doing since nine years of age. He gave no trouble in the ward other than to satisfy his great hunger and thirst he would take food from other patients' trays.

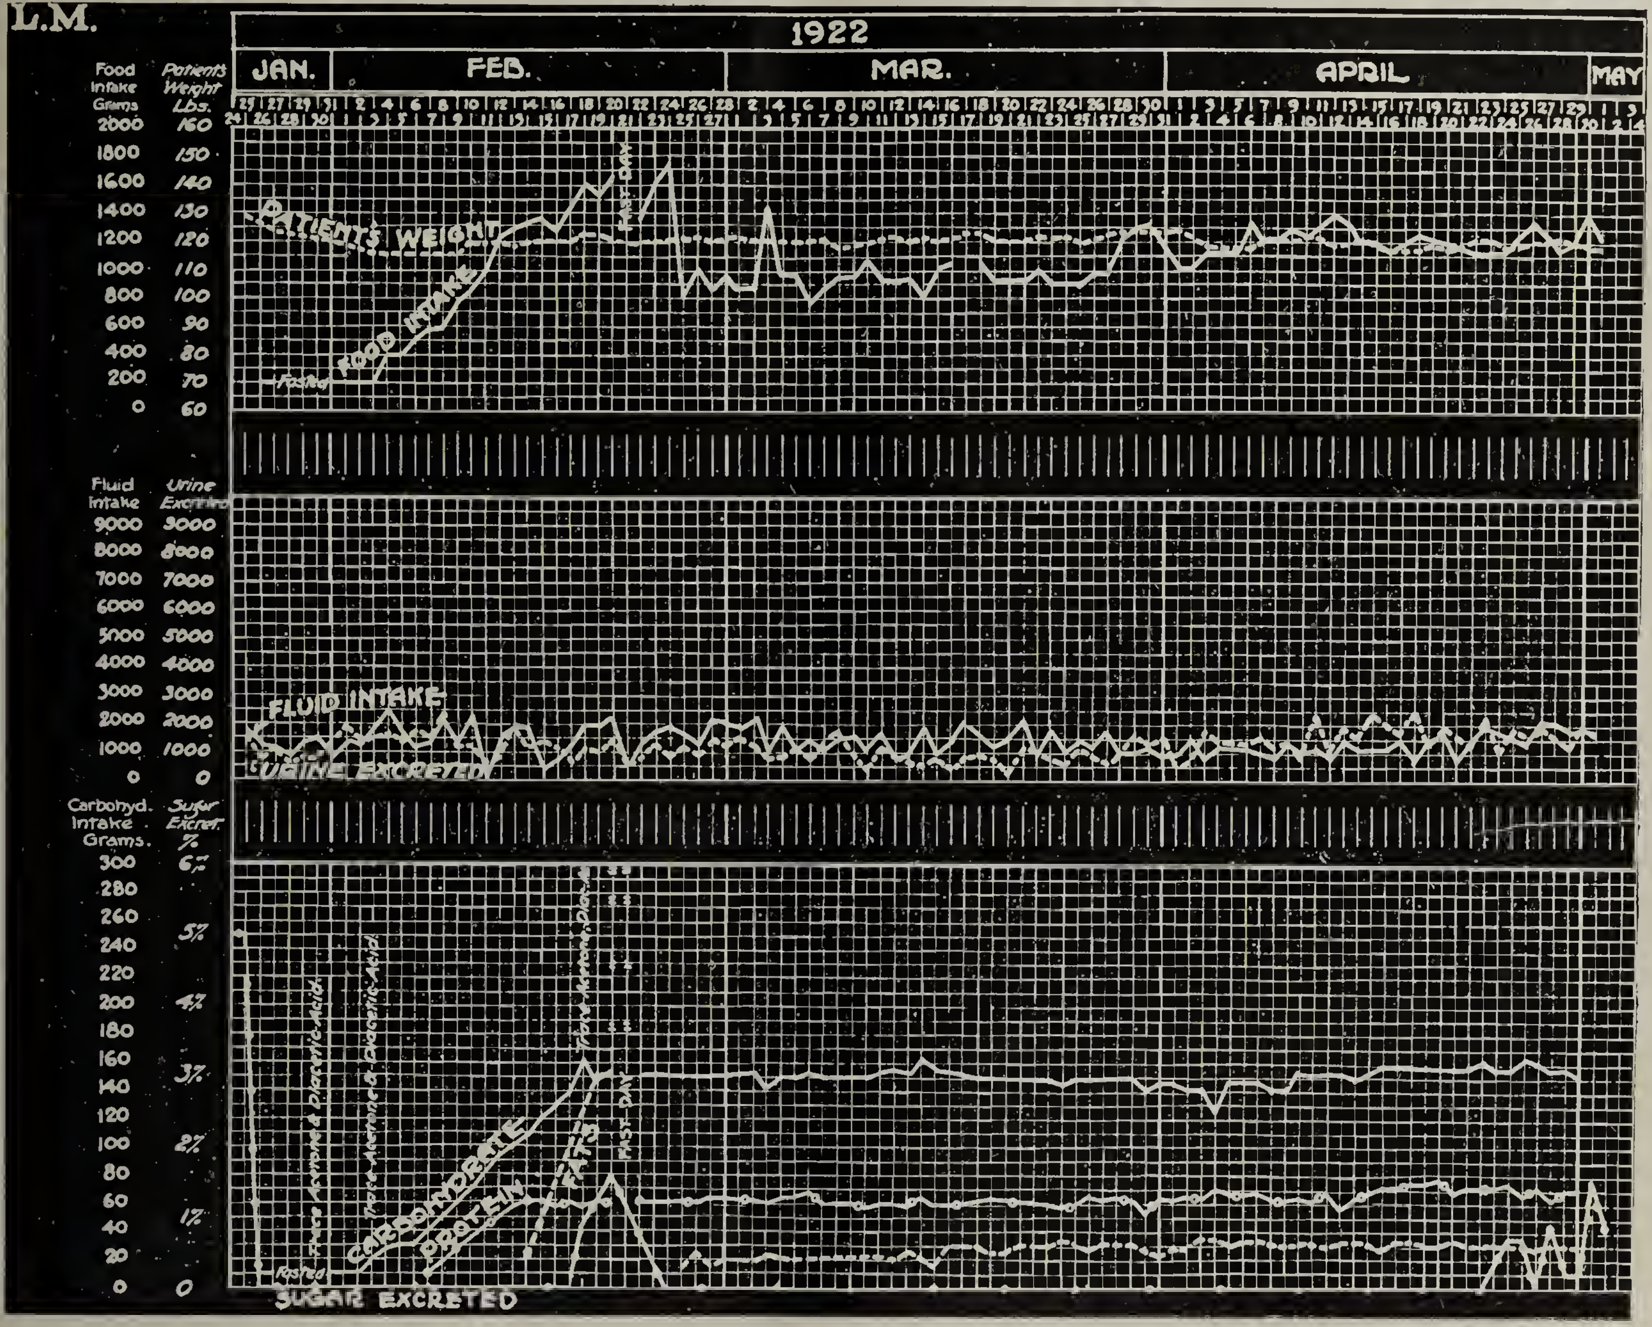

Chart II.—Showing patient's weight, food intake, fluid intake, amount of carbohydrate, protein, fats, in Case IV.

After a semifast of four days the Allen treatment was begun and since adhered to, with somewhat gratifying results. A more accurate chart had been kept. For each twenty-four hour period, the amount in c. c. of urine excreted; the amount of fluid intake in c. c.; carbohydrate, protein, and fats available in grams, gross weight of food in grams, weight of patient in pounds had been carefully noted. Blood sugar on November 30th was 0.31 per cent. The observations were upon a seventeen day period from December 3rd to 19th inclusive.

A glance at Chart I reveals a variable amount of urine excreted and a fluid intake most of the time above normal until within the last four days, December 16th, 17th, 18th, and 19th. Carbohydrate increased slowly from ten grams to eighty grams to the twenty-four hours had at no time caused a glycosuria. During the last four days protein had been added gradually in increasing amounts with impunity.

At the beginning of strict Allen treatment the patient weighed seventy kilos. Since a man at rest should get from thirty to forty calories to the kilo of body weight, the patient should have been getting 2100 calories for twenty-four hours. Instead of this he received forty calories and since then in gradually increasing amounts till on the 19th he received 512 calories. This, compared with his present weight, 21.4 per cent. of the calories value actually needed to keep up the body metabolism.

Notwithstanding that the patient was gradually losing weight at no time previous in our observation had the urine been sugar free and free from acetone and diacetic acid for as long a period as seventeen days. With the continued absolute cooperation of our patient, as far as he was concerned a negative quantity, but as to his treatment quite a positive one, hope of maintaining a good carbohydrate tolerance was entertained. Fats to the amount of 156 grams, protein 116 grams and carbohydrates to amount of 158 grams a day had been reached in his diet with no untoward symptoms, save the appearance of a trace of albumin once in the urine. The patient polished the floor vigorously each day; had a good appetite; ate and slept well and as near as can be observed was in good condition. Blood sugar, January 21, 1922, was 0.12 per cent. normal 06.-.11.

From January 23rd a careful note of the patient as regards diet was not kept. He received regular diet and continued working about the ward until his appetite became ravenous. Urine, examined at this time showed sugar present six per cent. Allen treatment begun again, February 16, 1922, but this time not successful due to the fact acute tuberculous pneumonia set in which was the cause of death, April 11, 1922.

Of interest is the pathological diagnosis from postmortem examintion: 1. Pancreatic diabetes. 2. General cerebral atrophy. 3. Acute tuberculosis pneumonia.

This case is one of proved diabetes mellitus in which the diabetes developed during the course of the psychosis and had no direct affect upon the patient's mental status.

CASE IV.—L. M. Upon admission to the hospital in December, 1913, the patient was fifty-one years of age. The urine was negative for sugar. Her medical certificate stated: "No drug or alcoholic habits in either parents or patient. Patient was of moderate disposition. Trouble began ten years ago, gradually increasing in severity. First symptoms: Hearing voices from various parts of the house. Became suspicious of everyone. Was fearful of being killed. Present symptoms: Constantly heard voices and seemed to think that someone had separated her brain into two parts and that she was being controlled by some invisible power. Probable cause: Excitement. Homicidal tendencies were marked. She had the impression that certain parties were trying to injure her and wanted to put them out of the way. Physical examination revealed a patient five feet, three and a half inches in height, weighing 133 pounds. An operative scar in the median line of the abdomen. Physical examination otherwise negative.

Further examination showed the patient's orientation for time, place and person good. Insight poor. Following an abdominal operation the patient began hearing voices day and night. Special memory tests fairly well performed.

In May, 1914, a uranalysis did not report sugar. At this time she was greatly upset by the voices; however, was neat and tidy in appearance and took an interest in her surroundings. Patient went to the sewing room for a half day, caused no trouble. From a note dated May, 1914: Patient was still hallucinated and the voices seemed to annoy her. She would carry on conversation with these imaginary people and became much excited. "They accused her of immoral conduct." Refered to the imaginary people as devils.

In July of the same year, the patient was brought to conference. Blamed her husband's employer for her troubles. Auditory, visual and tactile hallucinations annoyed her constantly. A diagnosis of a paranoid state was made in July, 1915, sugar was reported in the uranalysis. The Wassermann was negative. From the nurses' notes—Patient was pleasant and agreeable at all times, worked daily in special dining room, talked continually and fussed about the voices. Conversed with fellow patients, read and sewed. Doctor's note: Patient still reacted to her auditory hallucinations especially at night. She wanted the curtains pulled down and lights out so her enemies could not put too strong a charge of electricity on her. Lacked insight and could not be reasoned with in regard to her cystocele and rectocele.

June, 1919: Uranalysis at this time showed sugar to be present, the amount not reported. About this time nurses' notes recorded the patient as being disturbed at times, talked to herself, was tidy and attended to her personal needs. Refused to work in the general dining room, saying they didn't treat her right. Mention was made of an excellent appetite. Doctor's notes recorded the same hallucinations and mental troubles. December, 1919, a large amount of sugar was present in the urine. The patient continued up and dressed at usual hour, worked in general dining room, complained at times of feeling badly; conversed pleasantly with nurses and patients. Sleep disturbed at times. The patient continued to be delusional. During the day she was able to adjust herself fairly well to the outside environment; continued to help in the dining room, but in the evening when in her room, she was noisy, abusive and obscene in her remarks. Her delusional trend was along the line of persecution of herself and daughter. Her physical health was good although she suffered from a cystocele.

On July, 1920, patient was sent to the acute medical service for purposes of examination. Upon examination she was found to have had a hysterectomy and nothing surgical could be done for her. Patient was transferred back to her former ward. No mention was made of a uranalysis at this time.

In January, 1921, the patient weighed 140 pounds. Her attitude toward the physician was always friendly. She cursed the voices saying they were doing it all. June, 1921, the patient weighed 134 pounds; clean and neat; continued to talk to voices and remained about the same.

January 17, 1922, the patient was transferred to the acute medical service for purposes of examination and treatment, her chief complaint being bearing down pains in the pelvis.

With operative work in view, a routine analysis of urine was done and proved the presence of sugar. Sugar was present daily in the urine. On January 24, 1922, the patient was placed on Allen treatment for diabetes with good cooperation from patient. She seemed to understand her condition and was anxious to get well; worked about ward previous to beginning treatment and was quite happy although she complained of hearing voices.

During her diabetic treatment a daily chart was kept, urine excreted in twenty-four hours, fluid intake, total weight of food, available weight of carbohydrates, fats and proteins, patient's weight; sugar present in urine, etc. January 24th, five per cent. sugar was present in the urine. After a twenty-four hour fast, ten grams of carbohydrate were given for two days with such good cooperation, it was decided to fast the patient for three days, then feeding began with ten grams of available carbohydrate. Mention might be made here that no change in her mental symptoms occurred during the twenty-four hour fast period nor during the seventy-two hour fast.

Sugar disappeared from the urine and remained until the fats had, through oversight in the diet kitchen, been added too heavily to the diet. Sugar appeared in the urine six per cent. on the 18th of February and 1.0 per cent. on the 20th. With a fast day and reduced fats, the urine became sugar free on the 26th of February and remained so until the 21st of April. This day it appeared (amount not given). April 24th five per cent. sugar was reported, one and one half per cent on the first of May. The cause of reappearance was indulging the patient with white bread. Early in the treatment the patient weighed 129 pounds; lost about ten pounds and, as the chart shows, has with little variation held her weight, about 120 pounds.

Thus we have a patient first coming under daily observation with five per cent. sugar in the urine, eating well, feeling well other than a bearing down sensation in the pelvis and troublesome voices. During her first sugarfree period, January 25th to February 18th, the patient was somewhat weak, hence kept in bed, but quite in touch with all that was going on about her. Her greatest noticeable complaints were restricted diet and auditory hallucinations. She showed interest in the possibility of operation to cure her dragging down pains.

We were at this time dealing with a diabetic patient. However, previous to the onset of her somatic disturbance a certain group of mental symptoms were enumerated. She entered the acute medical service with an altered metabolism causing five per cent. sugar to appear in the urine. Notwithstanding her somatic upset of a severe grade the effect upon her mental self cannot be seen in either the increase of established mental symptoms nor the development of any new phases in her psychosis.

On February 18th sugar again appeared as related above. During this six day period metabolism was altered, but all that could be elicited from the patient was that she desired a few additional things to eat, but knew that the doctor knows best, and was willing to do without them.

For another period, February 24th to April 21st the patient was sugar free, was examined by the visiting gynecologist and found to be a nonoperative case. The uterus had been removed and a cystocele accounted for present symptoms. Patient had her same complaints, longing for sweetmeats, etc., remaining cooperative as before and eating that which was given her though she had access to more food if she chose. During this sugarfree period a blood sugar estimation on April 7, 1922, amounted to .087.

For a second time she was sugarfree, this time for nearly two months. During this period she was examined and told she was a nonoperative case for the present. She went on about her ward work, having the same interest in her relatives, asked to be transferred back to her former ward so that she might do work there as before.

For a third time she excreted sugar. The metabolism was severely altered as at first, yet no change in symptoms was elicited by daily observation of the patient.

I have been unable to note any change in the patient's psychosis during her periods of altered metabolism which could be definitely said to be dependent upon diabetes. In other words the somatic condition seemed to be a mere coincidence to her psychosis. In criticism one might say more frequent chemical blood analyses should have been done whereas only one preoperative one was done. However, daily urine examinations seem to be quite sufficient to note any serious changes in metabolism. Surely, those sufficient to cause a change in psychosis or give typical reactions in the patient's mental self.

The second case presents itself one in which diabetes mellitus is an associated condition with a psychosis of some years' standing. No direct relation between altered metabolism and mental symptoms could be observed.

SUMMARY AND CONCLUSIONS.

Needless to say before summing up the findings of the mental concomitants of diabetes mellitus that cases of glycosuria accompanying paresis are to be excluded. Whenever an abnormal condition is found in the body economy, whether it be one differing from normal in quantity or quality of reaction, internists are prone to attribute to it certain symptoms. Hence since sugar in the urine daily is an abnormal constituent bespeaking disturbed metabolism it is logical aside from finding organic derangements to look for morbid psychic changes.

It is a well known fact that certain organic diseases have a characteristic mental reaction in the individual, to wit, the well known unfounded hopeful attitude in a case of advanced pulmonary phthisis or the depressed case of advanced cancer. In diabetes mellitus we may have, aside from a definite psychosis, less organized, and less malignant psychic troubles. Among the exogenic psychic disturbances we note intellectual laziness, diminution of memory, hypochondriac preoccupations, hypoaffectivity with egocentric tendencies, and diminution of moral and physical energies.

Next let us consider the psychoses proper as associated with diabetes mellitus. First we find in the early report of these cases that patients so affected and psychotic were mostly melancholics. The literature up to the present day using different nomenclature, in the main, bears out the early findings. A depressed state of mind and a sense of ruin and worthlessness, are in the foreground in the greater number of diabetics having an associated psychosis.

However the physical and mental symptoms may be correlated, it is necessary to bear in mind three factors which play an important rôle in the development of a psychosis associated with diabetes; namely, arteriosclerosis, the involutional period and heredity. These offer excellent terrain for the blossoming and development of a mental disease.

In the first place, arteriosclerosis may be the causative factor of the patient's abnormal mental reaction. Again diabetes has a tendency to cause arteriosclerosis, in which case it would be a remote factor in the development of a psychosis. A third possibility is that the two may aid one another in the development of a psychosis. On the contrary either of the three possibilities may be present without any psychotic symptoms so that arteriosclerosis and diabetes are not the only vital factors necessary.

Secondly, the involutional period is given passing notice because of the tendency for a patient to go into a depressed state at this period. Also because the initiating factor in diabetes may be part of an internal secretory syndrome and at the involutional period there is a change in this biochemical regulating system.

Thirdly, heredity is mentioned since all the foregoing factors may be present and yet a psychosis not result in every case. It seems very logical that adding poor heredity to a case of diabetes mellitus we have added a strong psychic determinant in itself. Disregarding all other factors it is quite right reasoning from other cases of intoxication of exogenic or endogenic origin that a psychopathic taint is "the last drop in the bucket," to use the vernacular, in determining abnormal mental reactions.

Hence, when one or more of the foregoing factors are present the psychosis cannot be said to be symptomatic of diabetes mellitus without some conjecture as to what causative part the other one or more factors play.

In conclusion, it has been the observation of several clinicians that the mental symptoms in cases associated with diabetes cleared with the gradual disappearance of glycosuria. Paradoxical as it may seem one case in the literature stated that dieting caused a decrease in the glycosuria accompanied by more serious mental symptoms. These moderated when the patient was given full diet and as a result was excreting a high percentage of sugar in the urine. In others the disturbed metabolism caused no change in the mental symptoms. Cases of this kind are mentioned in the literature and the two cases studied by me were of this class. Last of all a psychosis appeared slightly before the disappearance of the diabetic affection and seemed to substitute for it. Therefore, before definite mental symptoms can be directly attributed to that form of brain intoxication accompanying diabetes mellitus, further study of selected cases with the free use of blood chemistry will be necessary.

Surgery in Diabetic Patients

By HARRY COHEN, M.D.,
New York,
Attending Surgeon, People's Hospital.

Of all conditions that confront the surgeon for advice and remedial measures, there are none so serious as those occuring in diabetic patients. When it is considered that diabetes is a common disease and that a large number of patients so afflicted sooner or later present some surgical complication, it can be seen that a difficult problem is presented. As in all other forms of surgery, considerable advancement has been made in the treatment of such cases, and among these the most epoch making has been Banting's discovery of insulin. The object of this paper is to review the latest work on this subject and if possible to formulate and systematize the method of treatment. The paper will necessarily be divided into two parts, namely, treatment of diabetes before and after the discovery and use of insulin. We shall review first the surgical status of diabetes before the use of insulin.

The rapid strides made in the studies of the internal secretions, the studies in the physiological chemistry of digestion, the Allen treatment, the studies in the blood chemistry especially in the prognostication of diabetes by the blood sugar estimation, and the estimation of the alkaline reserve and CO_2 coefficient have all placed the disease diabetes into a position where it can relatively be kept under control. In no form of diabetes are those factors of so great an importance as in the surgical complications of this disease, and in these remarks only the surgical element will be considered.

Let us enumerate briefly all the facts that are known to the surgeon when a patient suffering with diabetes presents himself for treatment. In the first place, to quote Murphy (1), "No class of patients is more prone to surgical complications, has less tendency to recovery, and less resistance to toxic infection than the diabetic." There are various degrees of diabetes, from the very mild to the very severe, the disease being more severe in the young. Again the disease may be stationary for a long time, but any complication upsets the metabolism balance.

Under proper medical management a severe case can be transformed to a mild one and kept under control for a long time. The urine is not a true guide to the severity of the disease, but the percentage of blood sugar is. The estimation of the

CO_2 coefficient, and the alkali reserves of the body are important. Foster (2) states that patients showing a hyperglycemia of over .35 per cent. or a CO_2 combining power of less than forty per cent. cannot be expected to survive any operative procedure. The two dangers are acidosis and coma, and coma is usually followed by death. Acidosis is more often the result of disturbed proteid and fat metabolism than that of the carbohydrates.

In diabetes surgical complications occur in two forms: First, where the complication is in an acute form and assumes the rôle of the main disease, all other considerations being of secondary importance, for example, acute gangrenous appendicitis; second, in the form where the complications are not so urgent, and in these cases with proper medical treatment, the prognosis is fairly good. Also, the complications are of two kinds, either infective or noninfective, an example of the latter being a hernia or a cancer.

In the infective variety, the prognosis is more than twice as bad as in the other kind. It is an accepted fact that in diabetes the resistance of the tissues to infection is slight, due to poor blood supply, the arteries, especially those of smaller calibre, being the seat of arteriosclerosis or more frequently endarteritis causing an ischemia. Krecke (3) found arteriosclerosis in all of twenty patients operated upon by him. The result is a spreading of the infection, suppuration and gangrene. In suppuration, healing takes a very long time causing a drain on the system with disturbed metabolism, acidosis, and frequently coma and death. Likewise, even where there is no infection, the tissues do not heal quickly, but take a much longer time than do ordinary wounds.

Another consideration is anesthesia. This, however, is no longer a subject for speculation; there are now rather well established rules to be followed in these cases. In the first place, chloroform must never be used, since it causes in these cases a fatty degeneration of the liver cells and is also a strong fat solvent throughout the body, causing acidosis and frequently coma. Ether, although also a fat solvent, is less dangerous, especialy when administered by the open method. In Berkman's (4) report of 159 cases in which the patients were operated upon at the Mayo Clinic, ether was administered 104 times. The anesthetic of choice is gas oxygen, with or without ether. In minor cases local anesthetics, especially procaine, should be used. Fitz (5) cites a mortality where a spinal anesthesia was used. It is well known that acidosis of a moderate degree may be present following any operation, especially a severe one. Therefore, in operating on the diabetic, the anesthetist should use every precaution.

Though not always the case, the majority in whom surgical complications have developed, are those that have neglected dietary treatment (6). When it is considered that dietetics is an important part of the treatment and that most surgeons know only the superficial elements of this subject, it is seen how important it is for the outcome of the case to place the patient as soon as he comes under observation under the care of an internist. Only the combined efforts of surgeon and internist will give the patient that chance for a good result to which he is entitled. The judicious use of the Allen treatment has saved several of my patients.

Of the surgical complications met with, gangrene of the lower extremities are the most common. In these cases amputation above the knee, with thorough premedical treatment, offers the most hope. But even then, the prognosis is grave. Gardner (7) reports a mortality of eighty per cent. in twenty-five cases in which operation was performed by him. The same is true about carbuncles and cellulitis. Absolute surgical cleanliness is essential. As for local treatment, baking and dry dressings have yielded about equally good results with wet dressings. In some cases the application of chlorazone paste has given good results. Occasionally pituitrin, administered hypodermically in doses of one c. c., has given good results by stimulating the circulation. I do not hesitate to use morphine for the relief of pain. Alkalies must be administered judiciously, in fact their use is condemned universally. The administration of a solution of sodium bicarbonate by hypodermoclysis is mentioned here only to call attention to the fact that it is never absorbed and whenever so administered always results in an abscess.

CASE REPORTS.

Case I.—S. G., aged thirty-nine, was admitted to People's Hospital, October 1, 1918, for an extensive carbuncle on the back. There was no acetonuria. The carbuncle was excised under ether anesthesia and active medical treatment instituted. The patient was cured in three weeks.

Case II.—T. K., female, aged forty-two, was admitted to People's Hospital, October 28, 1919, with a history of mild diabetes for several years past. She had been operated upon by me for internal and external hemorrhoids fifteen months previously, under local anesthesia. She was admitted this time for profuse menorrhagia of one year's standing. Under ether anesthesia a diagnostic curettage and an amputation of the cervix were performed. Immediately following the operation there was an increase in the glycosuria and acetonuria. The pathological report showed malignancy of the uterus and eleven days later a panhysterectomy was performed. She was placed under the medical care of Dr. Bieber. Soon after the second operation all symptoms of hyperglycemia with acidosis developed. The patient became increasingly drowsy and sleepy, but never went into coma. Active medical treatment reduced the glycosuria, the acetonuria and the hyperglycemia to .18 mg. and the alkaline reserve to 53. There was an infection of the wound but with chlorazone dressings this cleared up. The patient is well today, but adheres to strict dietary regulations.

Case III.—F. F., female, aged forty, consulted me on September 7, 1920, for beginning gangrene of the left toes. Sugar in the urine was 5.8 per cent. She was referred to the internist for medical treatment and in about three months the toes were normal again, and the urine became sugar free. On December 14, 1921, a gangrenous ulcer of the right foot developed, and sugar in the urine was three per cent. She was admitted to the People's Hospital and under active medical treatment with dry antiseptic dressing there was a considerable improvement in the ulcer, but she left the hospital before she was cured.

CASE IV.—A. T., aged forty-two, referred by Dr. Z. Zimmerman, was admitted to People's Hospital, April 17, 1921, for an extensive carbuncle of the back. The carbuncle was excised and under active medical treatment the patient made an early recovery.

CASE V.—R. F., aged sixty-five, was admitted to the People's Hospital June 11, 1921, for a diabetic gangrene of the left leg. Sugar in the urine was 3.4 per cent. Under treatment the sugar was reduced to one per cent and I amputated below the knee. Discharged from the hospital in four weeks, but was readmitted on August 30th with a gas bacillus infection of the stump extending up to the thigh. There was no increase of the gangrene, the diabetes under control, but the patient died as a result of the infection.

CASE VI.—A. G., aged forty-three, was referred by Dr. F. W. Klein, May 10, 1922. She had suffered from a mild diabetes for years, and recently an extensive erysipelas had developed extending over almost the entire body. Later, there was deep suppuration of the right leg, which was incised under local anesthesia (procaine). She made an early recovery.

CASE VII.—M. W., aged forty-five, was referred by Dr. J. Weiss, May 15, 1922. She had suffered from diabetes for years, but it was always under control. Most of the time there was no sugar in the urine. An erysipelas of the left leg developed, followed by suppuration with involvement of the ankle joint. An incision was made under local anesthesia (procaine). In this case Willem's treatment was instituted. The patient made an early recovery.

CASE VIII.—The patient, aged fifty-two, was referred by Dr. F. W. Klein, July 21, 1922, for beginning diabetic gangrene of the second toe of the right foot. Sugar in the urine 3.2 per cent. Active medical treatment by Dr. Klein resulted in the patient becoming sugar free. The toe was entirely healed and normal in appearance. This case was also complicated by an erysipelas of the face.

INSULIN IN SURGICAL DIABETES.

The care and treatment of the surgical diabetic since the advent of insulin or iletin presents not an entirely new picture but a rather vast improvement on the old methods described above. Medical diabetes and surgical diabetes, although the same fundamental disease, present the same differences in their treatment as has already been described. I can bear witness personally to all the wonderful results claimed for insulin in the treatment of the medical diabetic. I know of patients in coma who have been revived and who ultimately recovered; something I have never seen before in many cases. I have also seen an almost hopeless case with a very high blood sugar, extensive acetone and diacetic acid and with impending coma, in which vigorous and thorough dietetic treatment had been tried without avail, clear up on iletin in almost a week.

We are, however, not yet out of the woods as far as surgical diabetes is concerned, and I will briefly and very superficialy outline the results I have observed in the surgical diabetics under insulin treatment. In the first place, in cases of infection, the insulin seems to be destroyed, and to accomplish results much larger doses are necessary. I have seen a patient die of spreading gangrene of the leg with infection in whom insulin was being used. I will admit the coma that developed in this case was a much milder type from which the patient could be aroused. In this case no operation had been performed. In two cases of gangrene of the leg, insulin was used and the blood sugar and urine sugar were held in check. After amputation of the affected parts, the same dose of insulin appeared to have twice the effect, with the result that these patients made recoveries.

In each of these cases the result without insulin would probably have been fatal. As remarked before, this discussion of insulin will be a brief and superficial one. I have purposely omitted the detailed description of its administration for the following reason. The administration of insulin depends on the careful study of the blood sugar, sugar tolerance, diet etc. This can best be performed by the internist with the aid of the laboratory. I have consequently left this part for the internist to be described fully.

CONCLUSIONS.

Although the chances are always against the diabetic, still with proper diet and precautions surgical complications can in most cases be avoided or reduced to a minimum. Where such complications do occur, with vigorous preoperative medical treatment by a competent internist, the prognosis is considerably improved. Gas oxygen with or without ether or open ether is the anesthetic of choice in major operations and local (procaine) in minor. The operation in every case should be thorough and the medical treatment continued. In three of my cases erysipelas was a complication. As to what constitutes active medical treatment, especially preoperatively, I leave entirely to the internist, as this is in his domain. However, for those so desiring, Kahn (8) has written an excellent article. Concerning insulin, I feel that even in the present state of its use the results are wonderful, that the results in surgical cases are excellent, but that it should be administered by an internist. I see no reason, at least for the present, for relaxing in the strict observance of the diabetic diet. I am indebted to Dr. B. Dubovsky for many suggestions in regards to insulin treatment.

221 SECOND AVENUE.

Observations on the Nutritive Value of Pasteurized and Condensed Milk

By PHILIP B. HAWK, Ph.D.,
CLARENCE A. SMITH, Ph.D.,
and ROBERT A. LICHTENTHAELER, Ph.D.,
Philadelphia.

(From the Laboratory of Physiological Chemistry of Jefferson Medical College, Philadelphia.)

It was long ago abundantly demonstrated that milk was one of the most valuable of foods, and this importance of milk in the diet has been confirmed and emphasized by the more careful and scientific observations of the last few years. The inclusion of liberal amounts of milk in the diet has been shown to protect the individual against the possible protein, vitamine, and inorganic salt deficiency of the other foods eaten. The casein of the milk is a complete protein which supplements in this respect many common cereal foods whose protein is defective. A cereal meat diet is also deficient in the inorganic elements most needed by the body, calcium and phosphorus, and in its content of these milk excels. Vitamines A, B, C, and D are ordinarily present in milk in amounts sufficient to protect against disorders due to a deficiency of any of these in the diet.

There are, nevertheless, several reasons why the important dietary relationships of milk deserve more complete investigation. The character of the milk, especially with relation to its vitamine content, is influenced by the diet of the animal and hence generally undergoes seasonal variations, milk being generally richer in vitamines, and especially the antiscorbutic vitamine, during the summer period when good pasturage is available. Stall fed animals may produce milk rich in vitamines A and B if given suitable proportions of grains and leafy foods (1). It follows that butter produced during the summer and stored for winter use may be richer in fat soluble vitamine than fresh butter prepared from winter milk. Furthermore, it is quite possible that a condensed milk prepared during the summer may be richer in all or some of these vitamines than a fresh winter milk. Into this latter consideration, however, enters the question of the possible destruction of vitamines by the condensing process. Inasmuch as most of the fresh milk sold to the consumer has been pasteurized, the possible influence of this treatment is of interest, and the most practical idea as to the relative value of condensed milk should be obtained by comparing it with this most generally used form of milk with respect to content of vitamines, protein and inorganic salts.

In the case of infants and young children with rapidly growing bones, the inorganic metabolism is of unusual importance, and the diet must contain calcium and phosphorus in adequate quantities, in proper proportion, and in association with a vitamine found in codliver oil, butter, and certain other fats. There has been considerable speculation as to possible alterations in the inorganic composition of milk by boiling or by the lower temperature of the condensing process, as well as with regard to the influence of any such change or of the increased carbohydrate of condensed milk on inorganic nutrition. Only recently, however, with the development of animal feeding experiments, has there been much advance in our knowledge of the relationship of diet to bone growth. Many questions with regard to rickets remain unsolved, but no experimental evidence has yet been produced to show that condensed milk is not equivalent to fresh milk in the prevention of this disorder. McCollum, Simmonds, Becker, and Shipley (2) have shown that the antiscorbutic vitamine is far more resistant to heat and oxidation than vitamine A. A part of the present study was directed toward determining whether sweetened condensed milk led to any differences in the growth of the bones or teeth of rats as compared with pasteurized milk, as well as to determine the influence of a condensed milk diet on animals with well developed experimental rickets.

The ease of digestion of a milk is also an important consideration which may often overbalance minor differences in nutritive value. Undigested curds have been frequently noted in the feces as well as in the vomitus of children fed on raw or pasteurized milk. It has been shown by Brennemen (3) as well as in this laboratory (4) that these unmodified milks tend to produce large and indigestible curds in the human stomach. Boiling tends to reduce markedly the size of the curds formed. We report here experiments showing the character of the curd formation after ingestion of condensed milk as compared with pasteurized milk. We believe they throw distinct light on the special value of canned milks in infant feeding and in other connections.

ANIMAL FEEDING EXPERIMENTS.

Feeding experiments were conducted on albino rats to determine what, if any, differences existed between the nutritive values of, a, high grade pasteurized milk, and, b, sweetened condensed milk, and whether either or both of these were adequate and complete foods, especially with reference to the vitamines A, B, and D, to protein and to inorganic salts.

The plan of the experiments was to feed the pasteurized and condensed milks to groups of animals as sole foods, and if there was a failure of growth or normal bone development, to supplement this diet by the addition of any required factor. As the results show, the latter procedure was unnecessary. The findings on rickets were further checked up by experiments on rachitic animals.

Twenty young albino rats, carefully bred for experimental purposes by the Wistar Institute of Anatomy, were divided into two similar groups of ten rats each. All were female rats, and rats of the same ages and similar weights were equally divided between the two groups. The animals were kept under the best sanitary and entirely similar conditions. The experiments were carried out during the summer in order that the comparison might be made with summer milk of presumably higher vitamine content. The temperature of the animal room was kept constant except on the hottest days, when some temporary retardation of growth of all animals occurred, which was without effect on the general result.

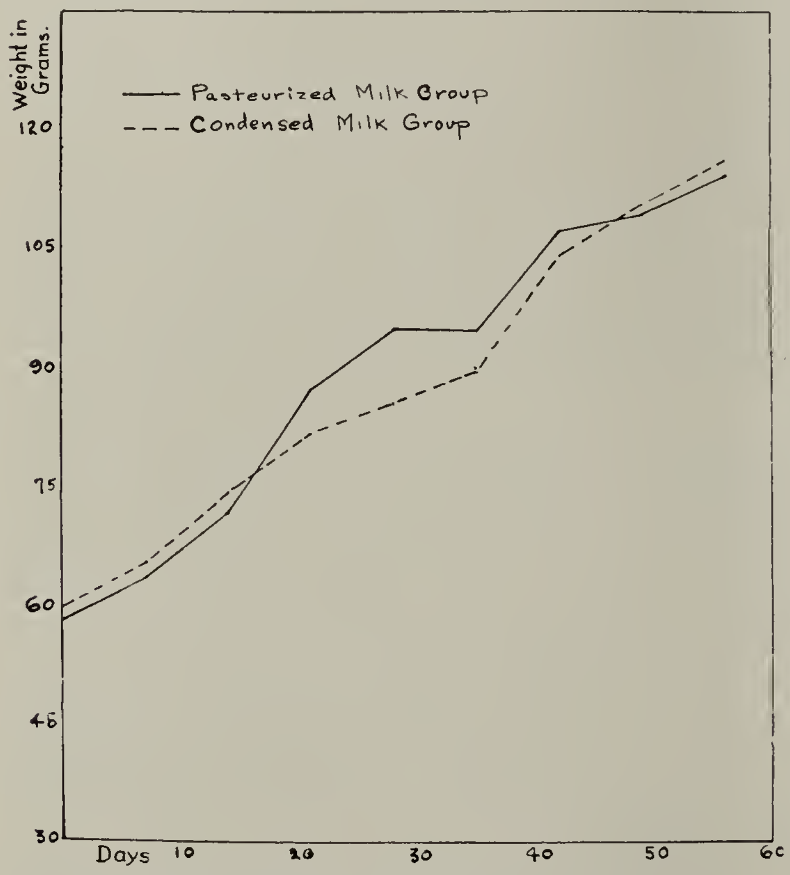

CHART 1.—Growth of rats on pasteurized and condensed milk. Average curves for ten animals in each group.

The pasteurized milk used had been heated for thirty minutes at a temperature of 60° C. It contained four per cent. of butter fat and was a better market grade, put out by probably the largest dairy supplying the city of Philadelphia and surrounding territory. The sweetened condensed milk used was diluted with two volumes of water before feeding.

All animals were weighed once a week throughout the eight weeks of the experiment. At the end of that time all animals were subjected to a general pathological examination for any rachitic tendency or any symptoms of vitamine or other dietary deficiency. Typical animals were studied more precisely; the examinations including microscopical study of the bone by an expert pathologist, of the teeth by an expert dentist, and the bones were also analyzed quantitatively for inorganic salts.

The average rates of growth for the ten animals in each group are summarized in Chart I.

It will be noted that the rats of both groups developed normally and increased in weight throughout the course of the experiment which covered the chief growing period of these animals during which any kind of milk could be expected to supply their whole needs. It has been shown that in the later periods of growth, milk must be supplemented by other foods (5).

Some differences were noted in the rates of growth of individual animals; but averaging the rates for all animals in each group, no particular differences obtained, i. e., the condensed milk rats did fully as well as those fed on pasteurized milk. Nor could any gross differences in the character of growth or development of particular tissues be noted. All animals appeared quite normal in every respect. There were no signs of any deficiency in the diet of vitamine A, vitamine B, or vitamine D, indicating that these were present in adequate amount and were presumably unaltered in amount by the treatments to which the milks had been subjected. Nor could the protein of the milk have been essentially altered in the condensing process.

It has been suggested by certain clinical writers that the inorganic content (especially calcium and phosphorus) of milk might be altered unfavorably in the condensing process or that the high carbohydrate content of this milk might in some way interfere with the metabolism of these elements in such a way as to lead to the production of rickets. Although rickets has been repeatedly produced in animals by a number of observers and on different diets, we know of no experimental support for the view that a condensed milk diet is in any way contributory to the development of this condition.

None of the animals reared by us on an exclusive condensed milk diet showed any signs of rickets when examined macroscopically. No differences could be noted in the development of bones or teeth of the animals of the two groups. As a further control, typical condensed milk rats (numbers 24 and 28 of this series), and a normal rat of similar age raised on pasteurized milk, were turned over to Dr. Edward Weiss of the pathological department for detailed and microscopical examination. The skulls of the same animals were given to Dr. Joseph Head of the dental department of the Jefferson Hospital. All animals were known to each of these observers only by number, i. e., the previous history of each rat was unknown to them.

The report of Dr. Weiss was as follows: "Autopsy on three rats, one control and two experimental, showed no gross evidence of bone change. Microscopical examination, femur of control rat. There is a regular narrow zone of ossification between the epiphysis and diaphysis. Ossification is apparently proceeding in a normal manner, both at the epiphyseal end and beneath the periosteum. The marrow substance shows no microscopic evidence of disease,

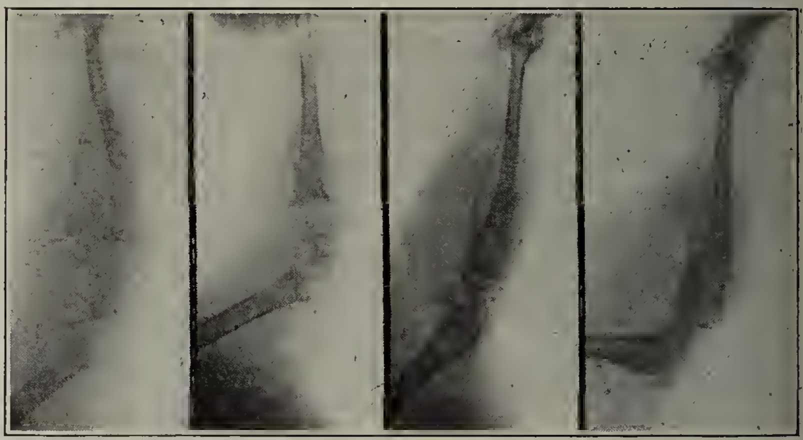

FIG. 1 FIG. 2 FIG. 3 FIG. 4

FIG. 1.—Control animal on rachtic diet.
FIG. 2.—Control animal on rachitic diet.
FIG. 3.—Rachitic animal after condensed milk feeding.
FIG. 4.—Rachitic animal after condensed milk feeding.

and the musculature surrounding this joint is apparently normal. Bone sections of experimental animals do not differ from the above." From this report it is apparent that the bones of the animals fed exclusively on condensed milk were histologically normal.

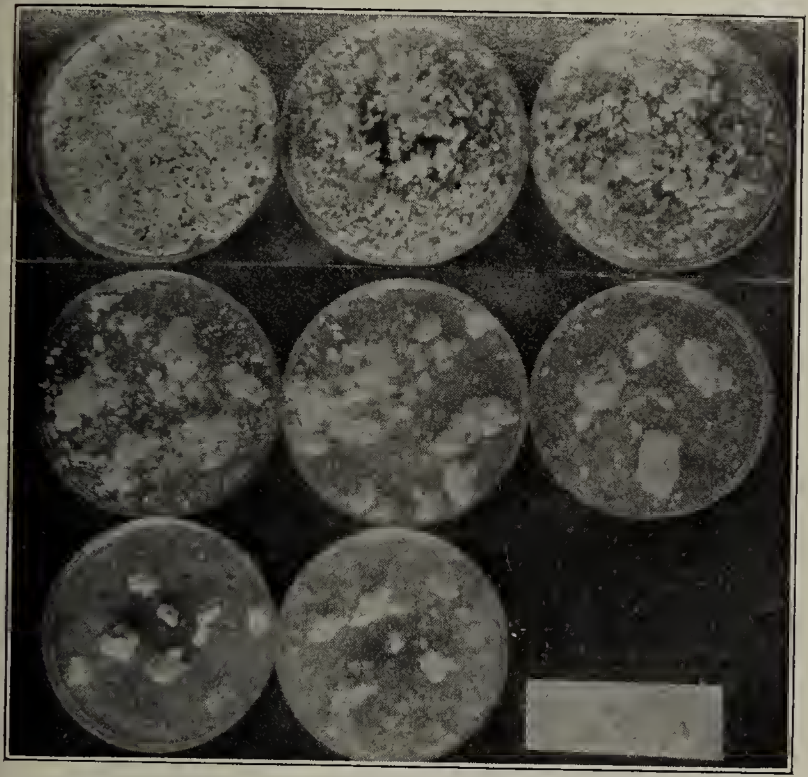

Fig. 5.—Curdling of pasteurized milk in the human stomach. Samples obtained 2.5, 5, 10, 20, 30, 40, 50, and 60 minutes after ingestion of 400 c.c. of milk.

The report of Dr. Head was as follows: "I have examined the teeth of rats number 1, number 2, and number 3 and find the teeth were firmly imbedded in healthy alveoli. The bone seemed to be of about similar strength and consistency. I find, however, that rat number 1 has much larger and better developed teeth than either rats number 2 or number 3. Rats number 2 and number 3 have teeth of approximately the same size and development, rat number 2 being a little the better."

Rat number 1 was the number 24 of our condensed milk series and number 3 our number 28, while number 2 was the control animal raised on pasteurized milk. From Table I, which gives the body weights of these animals at the beginning and at the end of the experiment, it will be seen that the rat with the best developed teeth was a condensed milk rat that had grown more rapidly than the control. Of the two rats showing teeth similar in size, the condensed milk rat was a slightly younger and smaller animal. All things considered, therefore, the condensed milk diet appeared rather better than pasteurized milk for development of the teeth.

As a further check on the anatomical findings, corresponding femurs of each of these three rats were carefully freed from ligaments, dried, and weighed. The bones were then ashed and the total ash of each determined. The results are given in Table I. It will be seen that of the two larger rats, which were of the same size at the beginning, the condensed milk rat had gained more in body weight, its bones were larger, the bones contained more ash, and a higher percentage of ash than the pasteurized milk rat. The smaller condensed milk rat, which was also a little younger than the rat fed pasteurized milk, had bones slightly smaller (but larger in proportion to weight), the bones, however, containing more ash and a higher percentage of ash.

The bones of the animals fed condensed milk only were, therefore, entirely normal in mineral content and compared favorably in this respect with the bones of a control animal fed pasteurized milk. The condensed milk evidently supplied all the requirements for normal bone growth in these animals.

It seems clear, therefore, that the condensed milk was entirely satisfactory as a source of calcium and phosphorus for the growth of bones and teeth and that no signs of rickets could be noted in animals fed exclusively on condensed milk which was as satisfactory in this respect as a high grade pasteurized milk.

It still remained to be shown whether or not condensed milk would bring about the healing of a severe rickets produced by defective diet.

McCollum and his coworkers have developed a diet which regularly leads to the production of a severe rickets in rats (6). This diet is low in phosphate and in fat soluble vitamine. It has the following composition:

Whole corn, ground	330	grams
Whole wheat, ground	330	"
Wheat gluten	150	"
Gelatine	150	"
NaCl	10	"
$CaCO_3$	30	"

In the present experiments eight young albino rats were fed on the above mentioned rachitic diet for forty days. Typical rickets developed as shown by symptoms and by the x ray photographs made of each animal. The wide bands of uncalcified cartilage at the ends of the long bones could be clearly made out in every case.

TABLE I.

ANALYSIS OF BONES OF MILK FED RATS.

Rat No.	1	2	3
Diet	*Condensed Milk*	*Pasteurized Milk*	*Condensed Milk*
Weight, beginning of experiment	74	73	60
Weight, end of experiment	138	120	108
Femur, dry weight	0.2800	0.2152	0.2060
Total ash	0.1892	0.1390	0.1406
Percentage of ash in bone	67.5	65.0	68.2
Ash, percentage of body weight	0.14	0.12	0.13

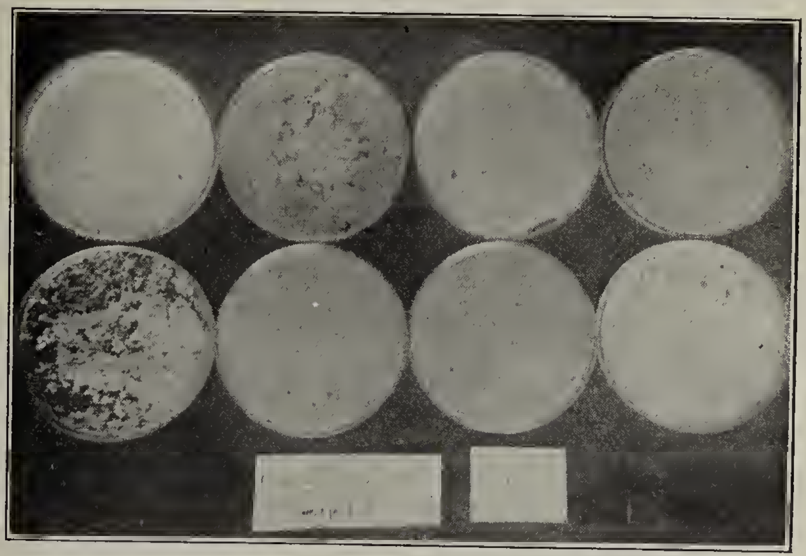

Fig. 6.—Curdling of condensed milk in the human stomach. Samples obtained 5, 10, 20, 30, 40, 50, 60, and 70 minutes after ingestion of 200 c.c. of milk diluted with an equal volume of water.

Four of the animals were left on the control diet, two were given with the control diet ten per cent. of butter, and two, five per cent. of butter; calcium and phosphorus were added to keep the percentage in the diet constant. Two were given only condensed milk for a period of seventeen days. The rats given condensed milk grew rapidly, whereas the controls made little growth. The butter fed rats were intermediate. See Table II for typical figures on control and milk fed animals. X ray examinations were made and showed the rickets to be entirely healed in the case of condensed milk rats, the uncalcified band having become completely calcified. The butter fed rats showed much less improvement. The control animals showed worse rickets than before. Typical x ray photographs of control and milk rats are shown in Figs. 1 to 4. All animals were kept throughout the experiment in a room never entered by direct sunlight. The x ray findings were checked, at the end of the experiment, by gross and microscopical examinations of longitudinal sections of the tibias.

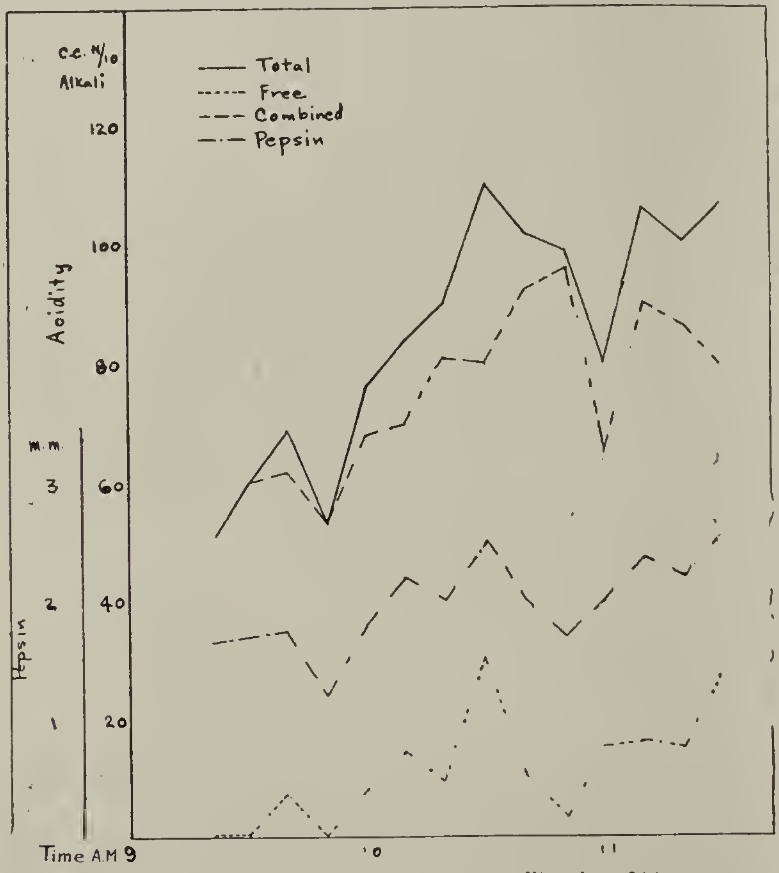

Chart II.—Two hundred c.c. condensed milk plus 200 c.c. water. Mixed 24° C.

TABLE II.

GROWTH OF RACHITIC RATS WITH AND WITHOUT CONDENSED MILK.

	1	*11*	*16*	*18*
Weight at start (grams)	52	56	58	81
Second week	58	71	71	105
Fourth week	57	74	93	112
Sixth week	52	77	92	117
	Condensed milk		*Rachitic diet.*	
Seventh week	72	83	104	120
Eighth week	95	101	105	119

Condensed milk, when given to rats with experimental rickets produced by a diet low in phosphate and vitamine D, brought about a rapid and complete healing of such rickets as shown by x ray examinations.

EXPERIMENTS ON THE DIGESTION OF MILK IN THE HUMAN STOMACH.

The coagulation of the casein of pasteurized and condensed milks in the human stomach was studied in a number of cases. In most of these cases the subject was caused to swallow a Rehfuss tube, four hundred cubic centimetres of milk being then given, and samples of the gastric contents withdrawn at intervals of from two to fifteen minutes until the stomach was empty. The curds formed with condensed milk were never so large that they could not be withdrawn through the narrow bore stomach tube. In every case with pasteurized milk nothing but clear whey could be removed, showing that large curds had been formed. Tests were, therefore, made on a subject who could regurgitate ingested milk at any desired time after ingestion and representative specimens of gastric contents were thus obtained. Typical illustrations of curd formation with pasteurized whole milk and sweetened condensed milk are given in Figs. 5 and 6.

It will be seen that pasteurized milk, like raw milk, formed in the human stomach a curd at first flocculent but soon aggregating into large, firm, and relatively indigestible curds. The condensed milk, on the other hand, yielded fine, soft curds, which did not agglomerate into masses and must hence be more easily digested by both infant and adult stomachs. Human milk we have shown forms fine, soft curds in the human stomach resembling, in this respect, condensed milk and differing markedly from raw and pasteurized cow's milk.

The course of the digestion in the stomach of condensed and fresh milks was further studied by titration of the samples obtained in the fractional analysis for free hydrochloric acid and total acidity and the determination of pepsin. The results of typical experiments are given in Charts II and III.

The chief differences between the acid curves on condensed and raw milk arise from the fact that raw milk forms large curds which then combine slowly with the hydrochloric acid of the gastric juice. The free acid is, therefore, high, and the combined acid low compared with the findings on condensed milk, which forms fine curds, combining readily with acid and leaving less free hydrochloric acid. The secretion of pepsin was fully as great on condensed as on raw milk.

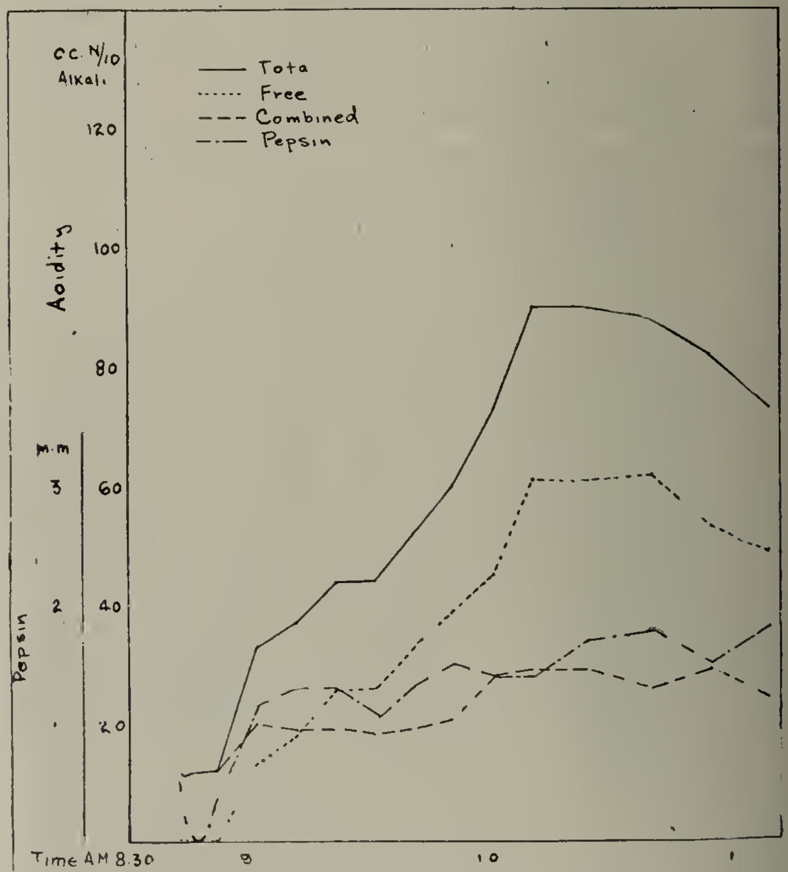

Chart III.—Four hundred c.c. raw whole milk. Temperature 20° C.

From the high combining power of condensed milk for hydrochloric acid and the low free acid figures found after ingestion of this food, we would expect condensed milk to be an especially useful form of milk to administer in hyperacidity and gastric ulcer. We expect to test out this possibility and mention it here only in the hope that others also may be led to try it out and report their findings.

SUMMARY AND CONCLUSIONS.

1. Sweetened condensed milk was found to be as satisfactory for the growth and development of albino rats as a high grade pasteurized fresh milk obtained during the summer season when such milk is generally considered to possess its maximum nutritive value. The content of vitamines A, B, and D and of protein must have been essentially unaltered by the method of preparation.

2. Condensed milk was as satisfactory for the growth of bone and the development of teeth as pasteurized fresh milk. There was no tendency towards the development of rickets. The total bone weight and the percentage of inorganic matter in the bone were at least as great on the condensed milk diet.

3. Condensed milk, when given to rats with experimental rickets, produced by a diet low in phosphate and vitamine D, brought about a rapid and complete healing of such rickets, as shown by x ray examinations.

4. Condensed milk formed finer and softer curds in the human stomach than pasteurized milk. Fractional analyses of gastric contents showed a more rapid combination of the proteins of condensed milk with the secreted acid.

Some Points in the Examination of the Heart for Life Insurance*

By FREDERICK W. PRICE, M. D., F. R. S., Edin.,
London,
Physician to the National Hospital for Diseases of the Heart; Senior Physician to the Royal Northern Hospital, London.

(*Continued from page* 561).

When a history is elicited of a marked increase in the cardiac rate, attacks of palpitation, occurring suddenly and without apparent cause, or of dyspnea on exertion and other indications of cardiac failure coming on rapidly, we should consider the possibility of paroxysmal tachycardia. By paroxysmal tachycardia I mean a condition in which a marked acceleration of the cardiac rate occurs, which commences suddenly and abruptly and without apparent cause, lasts for a varying period, ceases suddenly and abruptly, and is due to an abnormal rhythm—the stimulus for cardiac contraction, instead of arising at the junction of the great veins with the auricle, having its origin at an abnormal point. The return of the cardiac rate to what it was prior to the paroxysm is due to the reversion of the cardiac rhythm to the normal. From the definition given, it will be seen that paroxysmal tachycardia does not include acceleration of the cardiac rate associated with the normal or sinus rhythm. The paroxysm may last for only a few beats, or may persist, more rarely, even for months.

The vast majority of cases of paroxysmal tachycardia are due to, 1, temporary auricular flutter, or 2, temporary auricular fibrillation. The rhythm may be quite regular, in which case the cause is probably an attack of auricular flutter in which there is a constant and uniform ratio ~~between~~ the auricular and ventricular rate; or very irregular, when the condition is due to auricular flutter in which the response to the ventricular contraction is at irregular intervals; or completely irregular, when the result of a temporary attack of auricular fibrillation. A characteristic feature of the condition is that with the sudden reversion of the rhythm to the normal there is an extraordinarily rapid recovery to the state in which the patient was prior to the paroxysm; this may take place even within a few hours. Polygraphic or electrocardiographic examination will put the diagnosis beyond all doubt. But frequently neither of these is available, and, therefore, we have to trust to other methods of investigation.

The most important points from the diagnostic point of view are: 1. The commencement and termination of the attack of tachycardia. The suddenness and abruptness of the onset and termination of the tachycardia are a characteristic feature—the maximum rate is attained within a few seconds, and the return of the cardiac rate to what it was prior to the attack takes place equally quickly, whereas in tachycardia associated with a normal rhythm, the onset and termination are gradual. 2. The cardiac rate. A persistent rate of over 160 is almost invariably due to an abnormal rhythm, and a persistent rate of over 140 may be due to the same cause. 3. The cardiac rate is not influenced by change of posture or other forms of physical exertion, as is the case in tachycardia not associated with an abnormal rhythm.

The term bradycardia may be used in two different senses, namely, it may be restricted to infrequent action of the heart as a whole, the auricular rate being diminished *pari passu* with that of the ventricles; or it may be employed to denote infrequency of the pulse rate at the wrist, including that due to

---

*Read at a meeting of the Life Assurance Medical Officers' Association, London, January 4, 1921. The substance of this paper was published in a recent issue of the *Lancet*.

extrasystole, partial or complete auriculoventricular block, or even auricular fibrillation or auricular flutter, and the importance of this latter group of cases as causes of infrequency of the ventricular rate should be noted. I employ the term in the former sense. Using the term in this sense, bradycardia may be physiological, especially in males; in some perfectly healthy individuals the normal pulse is always infrequent, a pulse rate of 50 not being very uncommon, and, indeed, cases have been recorded of a pulse rate of 40 in a healthy individual. A pulse rate of between 50 and 60 is comparatively common among atheletes who are in training. Among the diseases in which the pathological form of bradycardia is met with are aortic stenosis, fatty degeneration of the myocardium, during the convalescence of acute infectious diseases, especially influenza, and jaundice.

The character of the pulse wave.—With regard to this, it is not necessary for me to draw attention to the diagnostic value of the "collapsing," the water-hammer or Corrigan's pulse, except to say that the collapsing character may be intensified by raising the arm above the head, and this method of examination should always be employed in suspected aortic regurgitation. But I would bring to your notice the valuable help which may be obtained from the character of the pulse wave in aortic stenosis and in mitral stenosis. The characteristic features are generally to be observed by careful palpation of the pulse, and, of course, always by the use of the sphygmograph. In aortic stenosis the pulse is sometimes very characteristic, being infrequent, of smaller amplitude, exhibiting an oblique percussion wave, and a gradual and slow summit, while to the finger the pulse is full between the beats (Fig. 2). It may be anacrotic or of the bisferiens type. A similar kind of pulse is sometimes met with in supernormal blood pressure with atheroma, and in aneurysm. Usually the pulse in mitral stenosis is small, the upstroke being short and soon attaining its maximum, the pulse wave is long, dicrotism is absent, and the pulse is full between the beats—in contrast with cardiac dilatation.

IRREGULARITY OF THE PULSE.

Irregular action of the heart in persons who may or may not exhibit evidence of organic disease is a subject of the utmost importance in the examination of the heart for life assurance. It is a problem which has been admittedly a source of perplexity and difficulty to the clinician. It was known that cardiac irregularity might signify serious impairment or disease of the heart on the one hand, or that it might be of little or no importance; for it was found that some patients lived the normal span of life without symptoms of cardiac failure, while others died perhaps after a lapse of only a few years. The difficulty arose from the fact that until recently it was impossible to determine the significance of the irregularity in any given case. All this is now changed; the problem has for the most part been solved; for it is now possible to classify the vast majority of cases of cardiac irregularity and it is known what each type signifies. We have, therefore, clear and certain grounds for purposes of diagnosis and prognosis. I would, therefore, respectfully emphasize the fact that it is not sufficient to have a question on the examination form, or to determine at the time of the examination, merely whether the pulse is regular or irregular. It is necessary to determine the type of irregularity, and we should be acquainted with the significance of each type.

All cases of cardiac irregularity, apart from comparatively rare exceptions, fall into one of six groups: 1. What is called sinus irregularity—a common type; 2, irregularity due to extrasystole, likewise common; 3, irregularity due to depressed conductivity—partial or complete heart block; 4, irregularity due to the pulsus alternans; 5, irregularity associated with auricular fibrillation, which accounts for approximately fifty per cent. of all cases of persistent irregularity of the heart; and 6, irregularity associated with auricular flutter.

In order to have a right understanding of the various forms of irregular action of the heart, it is necessary to bear in mind certain anatomical and physiological considerations: That part of the auricle which is situated at the junction of the chamber with the great veins is called the sinus part of the auricle; in it there is a small node of specialized tissue, called the sinoauricular node. There is another small node of specialized tissue situated in the septal wall of the right ventricle; this is called the auriculoventricular node. Leading from this node is a bundle of tissue connecting the auricles and ventricles, called the auriculoventricular bundle, or the bundle of His or Flack. As indicated, it arises above in the auriculoventricular bundle, and at the upper margin of the intraventricular septum this bundle divides into two branches, the right and left septal divisions, one of which goes to the right and the other to the left ventricle.

Now, when the heart is going to contract, the stimulus for contraction rises normally at the orifices of the great veins, that is, at the sinus, and it is probable that it begins in the sinoauricular node. From this point the stimulus spreads rapidly over the auricles, and auricular systole takes place. It then travels through the auriculoventricular node, along the auriculoventricular bundle, and is so distributed to the ventricles. Normally, therefore, stimulation and contraction of the sinus, auricles, and ventricles occur in the order named, the ventricle contracting only in response to stimuli received from the auricle through the auriculoventricular bundle. But, while normally the stimulus for contraction arises in the sinus part of the auricle, if any other portion of the heart becomes more excitable—as it may do in abnormal conditions—the stimulus for contraction arises at that particular point.

The stimulus for contracting is conveyed from fibre to fibre by means of a specialized function of the muscle fibres called conductivity; by conductivity is meant the power of conveying the stimulus for contraction from fibre to fibre. We can measure conductivity by means of the clinical polygraph and the electrocardiograph. All we have to do is to measure the time between the commencement of the systole of the auricles and that of the ventricles. Defects of the auriculoventricular junctional tissues give rise to varying degrees of heart block.

The great advance in our knowledge of irregular action of the heart has been almost entirely due to the introduction of the clinical polygraph and the electrocardiograph; for by means of these instruments we are able to obtain records of the movements of both the auricles and the ventricles, and also to make out the time relations of the contraction of these chambers. But what I want to emphasize is the fact that while most of our knowledge is the result of investigations which have been conducted by means of these instruments, the work of elucidation having been done, for practical purposes the use of these instruments is now not necessary in the great majority of cases of irregular action of the heart, all that is required being skilled employment of the ordinary methods of examination, particularly miscultation, and in a still larger proportion of cases—indeed, in the vast majority—the use of a Dudgeon's sphygmograph. In this connection may I commend the superior advantage of auscultation at the apex over other methods of physical examination in endeavoring to determine the rhythm of the cardiac action.

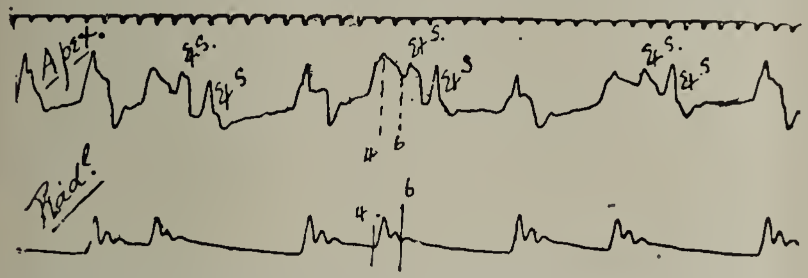

Fig. 1.—Simultaneous tracings of the apex beat and of the radial pulse, from a case with extrasystoles. The extrasystoles, eight in number, failed to send pulse waves to the wrist.

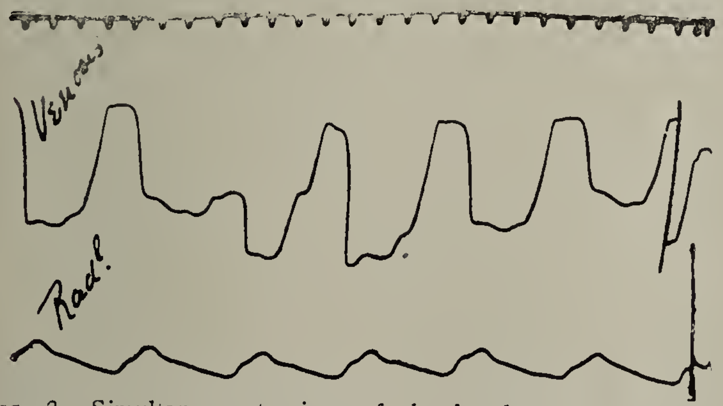

Fig. 2.—Simultaneous tracings of the jugular and radial pulses, from a case of aortic stenosis.

Sinus irregularity.—In sinus irregularity the stimulus for contraction arises at the normal site, namely, at the junction of the veins with the auricles, but the rhythm of the sinus is not regular. The condition is much more frequently met with in the young, but it may occur at all ages. There is a variation in the length of the diastolic period of the cardiac cycle, the systolic period remaining constant. On auscultation, therefore, the interval between the first and second sounds is found to be constant, while the varying length of the diastolic interval can be detected. If a tracing of the radial artery be taken, the intervals between the beats are found to vary; but the actual variations are not numerous, and the pulse beats are of equal or nearly equal size (Fig. 3). There is usually a definite relationship to respiration. The irregularity is most marked during slow respiration, and, indeed, may only be noted on deep breathing. When irregularity of the cardiac action is found to be definitely related to respiration, it is in all probability of the sinus type.

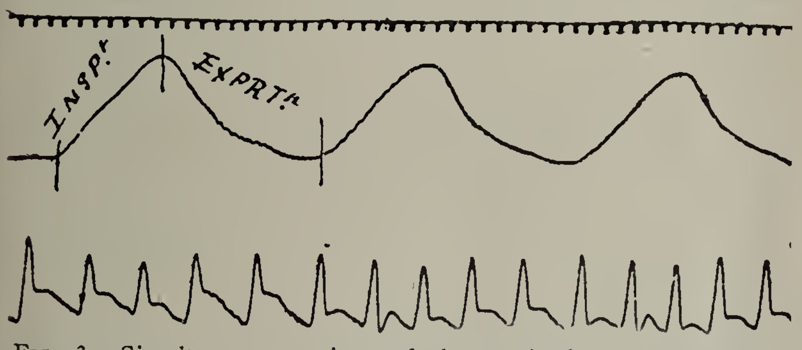

Fig. 3.—Simultaneous tracings of the respiration and the radial pulse, from a healthy boy, aged fourteen, showing sinus irregularity.

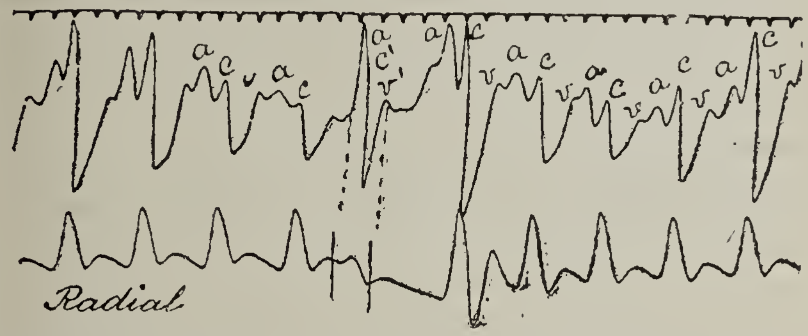

Fig. 4.—Simultaneous tracings of the jugular and radial pulses, showing an extrasystole. The extrasystole is synchronous with the systole of the auricle (ac').

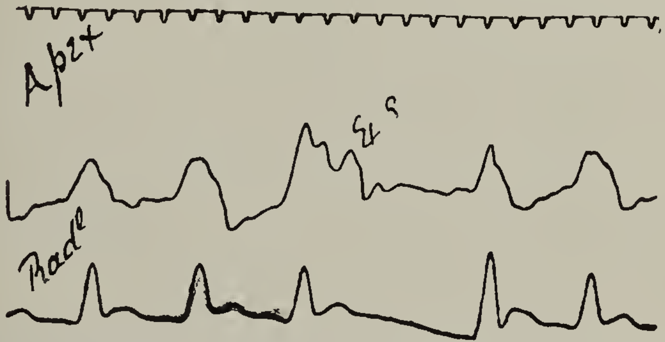

Fig. 5.—Simultaneous tracings of the apex beat and of the radial pulse, showing intermission of the pulse, due to a ventricular extrasystole failing to send a wave to the wrist.

What is the significance of sinus irregularity? There is no reason to suppose that it is either indicative of an impaired heart, or that it adds to the gravity of any diseased cardiac condition which may be present. The condition may, therefore, be totally disregarded in an examination for life insurance.

The extrasystole.—By extrasystole is meant the premature contraction of the auricle (auricular extrasystole), or of the ventricle (ventricular extrasystole), or of both chambers together (nodal extrasystole), while the fundamental or sinus rhythm is otherwise maintained in most cases (Fig. 4). Extrasystole may appear at long, or at frequent irregular intervals, or regularly after each beat, or after every second, third, or more normal beats. In most cases the pause which follows the premature contraction is abnormally long, being called the compensatory pause, and the pulse beat immediately following a compensatory pause often has a greater amplitude than on other occasions.

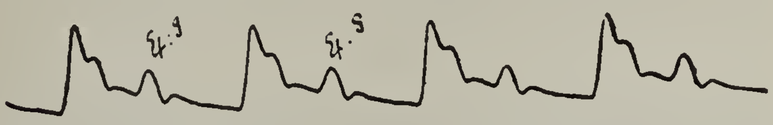

Fig. 6.—Pulses bigeminus, due to a single extrasystole with its succeeding compensatory pause occurring regularly after each normal beat.

On auscultation, in the vast majority of cases two heart sounds are synchronous with each extrasystole. Sometimes, however, the extrasystole occurs early in diastole, and before the cardiac muscle has had sufficient time to recover fully from the preceding systole, in which event the premature contraction is so feeble as to fail to open the aortic valves, and only the first sound is heard. Very rarely the premature contraction is so feeble as not to produce any cardiac sounds whatever. An extrasystole may be so feeble that no wave is felt at the wrist, so that there is simply an abnormally long pause, resulting in what is called a dropped beat or an intermittent pulse. By far the commonest cause of an intermittent pulse is an extrasystole which fails to reach the wrist (Fig. 5). If a single extrasystole with its succeeding compensatory pause occurs regularly after each normal beat, then the beats at the cardiac apex occur in pairs, as also do the pulse beats (Fig. 6), the latter condition being called pulsus bigeminus.[1] If a single extrasystole with its succeeding compensatory pause occur after every two normal beats, then the apex beat occurs in threes, as also do the pulse beats, the condition being known as *pulsus trigeminus;* but if the premature contraction is so feeble that no wave reaches the wrist, the pulsebeats are paired (pulsus bigeminus). If an extrasystole occurs regularly after each normal beat and the extrasystole fails to reach the wrist on each occasion, the rate of the arterial pulse is halved. The next most common cause of an intermittent pulse is partial heart block (Fig. 7). Pulsus bigeminus (Fig. 8), pulsus trigeminus and halving of the pulse rate may also be caused by partial heart block.

In the great majority of cases a correct diagnosis of extrasystoles can be made simply by palpation and auscultation, especially the latter. The differential diagnosis between intermission of the pulse, pulsus bigeminus, pulsus trigeminus and halving of the pulse rate, due on the one hand to extrasystoles and on the other to partial heart block, can as a rule readily be made by means of palpation and auscultation. In the former case a premature beat can be detected at the apex beat, and on auscultation one or two heart sounds will, in the vast majority of cases, be audible during the early part of the pause, because the ventricle has contracted; whereas in the case of partial heart block, there will be absence of an apex thrust and of heart sounds during the pause, because the ventricle has failed to contract.

Extrasystoles may be met with at any age, but they are much more frequent in the middleaged and elderly than in the young. Extrasystoles are of more common occurrence in men than in women, and are also more usual in the subjects of heart disease than in those who are not, and are more frequent in myocardial degeneration than in valvular disease. But it should be remembered that there is a large group of cases in which extrasystoles are present without any other manifest cardiac abnormality. They are to be found, for example, in persons with a history of rheumatic infection, the victims of tobacco poisoning, in digestive disturbances, supernormal blood pressure, neurasthenia, and as a result of the administration of certain poisons, especially digitalis and aconitine; in some cases no cause is ascertainable.

What is the prognostic significance of extrasystoles? They indicate that some portion of the heart below the sinus is more excitable than the sinus. In 1911 I wrote that when extrasystoles are considered by themselves—that is, without reference to the conditions with which they might be associated—there was so far no evidence for supposing that they were either indicative of an impaired heart or that they added to the gravity of any existing morbid condition. Further experience has not led me to change that opinion, and, therefore, for life insurances I should base my opinion entirely upon the associated conditions and take no notice of their presence alone.

Depressed conductivity—partial and complete heart block.—There are three degrees of depressed conductivity: 1. There is merely a prolongation of the interval which separates the commencement of contraction of the auricle and that of the ventricle, each stimulus of the auricle reaching the ventricle, which duly responds. 2. The stimulus does not always reach the ventricle; in other words, the ventricle does not always respond to the stimulus from the auricle. 3. No impulses reach the ventricle from the auricle, so that the auricles and ventricles beat independently of each other; the former in response to stimuli received from the sinus, and at an approximate rate of 73 a minute, and the latter as the result of stimuli arising in its own wall, at about 30 a minute, because this is the normal ventricular rate. The first two degrees are called partial heart block and the third is called complete heart block.

The first grade of heart block may give rise to irregularity of the pulse, on account of variations in the length of the intervals between the contraction of the auricles and of the ventricles. In my opinion this grade can only be recognized by means of the polygraph or the electrocardiograph. The second degree of heart block may give rise to dropped beats, pulsus bigeminus, pulsus trigeminus, and halving of the ventricular rate. The differential diagnosis from extrasystoles has already been dealt with. The higher grades of heart block give rise to infrequency of the pulse rate. When the ventricular rate suddenly falls to half its former rate, in all probability the case is one of two to one heart block. In complete heart block the pulse rate is slow, not infrequently being between 20 and 30 beats a minute, and usually not more than 36, though some cases have been recorded in which the rate has been considerably higher—even up to 60 beats a minute.

It is sometimes difficult to distinguish between partial and complete heart block without the aid of the polygraph or electrocardiograph. Most cases with a ventricular rate of 36 or under, however, are cases of complete heart block. Also the presence of more rapid pulsations in the jugular veins than the rate of the radial pulse, and the presence of small waves occurring at regular intervals on the descending limb of a sphygmogram afford help in differential diagnosis. Persistent heart block of mild degree is indicative of myocardial damage.

Pulsus alternans.—By pulsus alternans is meant a condition of the pulse in which, while the rhythm is perfectly regular, a large beat and a small beat alternate (Fig. 9). In the vast majority of cases it is necessary to take a tracing of the radial artery in order to recognize the condition. When pulsus alternans occurs in association with the normal rhythm, it is an indication of extreme exhaustion of the heart muscle; when the condition lasts for only a few cycles, this exhaustion may be only temporary, but even in these cases the prognosis should be guarded; when it is continuous, death may follow within a few months, or at most in a few years. When the condition is associated with an abnormal rhythm, such as auricular flutter, it does not appear to have any serious significance in itself.

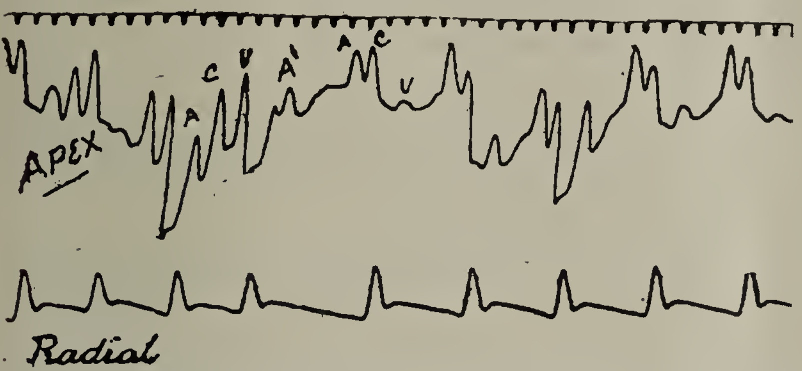

Fig. 7.—Simultaneous tracings of the apex beat and of the radial artery, showing the intermission of the pulse, due to partial heart block, the ventricle failing to respond to the stimulus of the auricle at A′.

Auricular fibrillation.—It is of the utmost practical importance with regard to life insurance that auricular fibrillation should be recognized. It accounts for approximately fifty per cent. of all cases of persistent irregularity of the heart. When auricular fibrillation has once set in, it persists for the remainder of life in the great majority of cases. It results in an irregular, and, in most cases, a much too frequent pulse. Such a change in the action of the ventricle, as a rule, produces a considerable effect on the heart's efficiency, and when the ventricular rate is much above the normal, symptoms are usually present and these are the same as those of cardiac failure from other causes. There is a wide variation in the ventricular rate, this ranging from 40 to 140 or even 180 a minute, the average rate being between 90 and 140. The ventricular rate should in every case be counted at the apex, either by palpation or auscultation, preferably the latter, as the rate of the radial pulse does not necessarily represent the ventricular rate, for many beats of the heart may not be transmitted to the wrist, especially when the ventricle is beating rapidly. As already stated, the pulse is irregular, and the irregularity represents the following features, which are of profound importance for diagnosis:

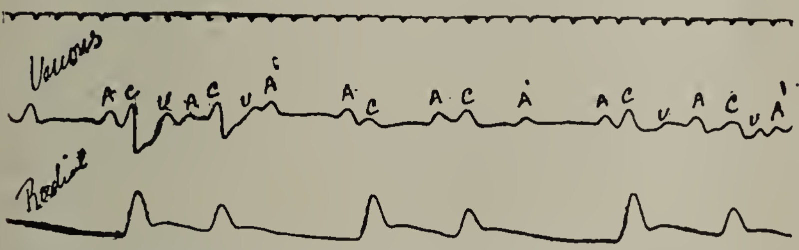

Fig. 8.—Pulses bigeminus, due to partial heart block, the ventricle failing to respond to the stimulus from the auricle at A′.

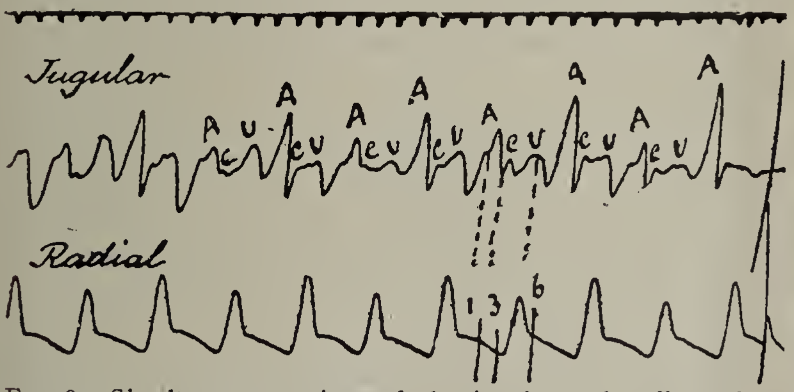

Fig. 9.—Simultaneous tracings of the jugular and radial pulses, showing continuous pulsus alternans.

1. It is always continuous, and in the great majority of cases it persists for the rest of the patient's life, in this respect differing from most other types of irregularity. 2. A feature of even greater importance is the fact that the irregularity is complete; it is an irregularly irregular pulse (Fig. 10). Two pulse beats of the same length or size rarely follow each other. There is often no relation between the length of a pause and the strength of the beat which follows it, i. e., a short pause may be followed by a strong beat, and a long pause by a weak beat. The beats may be coupled[2] for long or short periods, and this may occur independently of the action of digitalis, although it is usually due to it. This type of irregularity can usually be differentiated from the other types by palpation of the radial pulse and of the apex beat, and still better by auscultation at the apex. When the ventricular rate is slow, or very rapid, it may be necessary to take a sphygmogram and to adopt careful measurements.

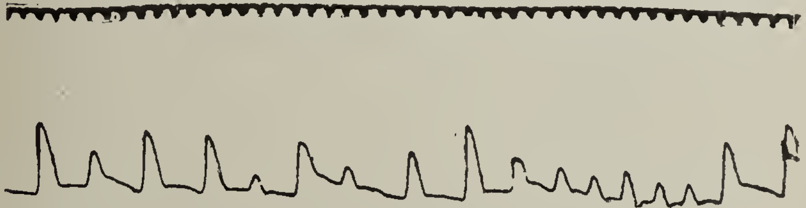

Fig. 10.—Tracing of the radial pulse, from a case of auricular fibrillation, showing complete irregularity of the pulse.

A diagnosis of auricular fibrillation may be made by means of the clinical polygraph or by the electrocardiograph. What I wish to emphasize is that we may be reasonably certain of its existence from the mere presence of complete irregularity of the pulse.

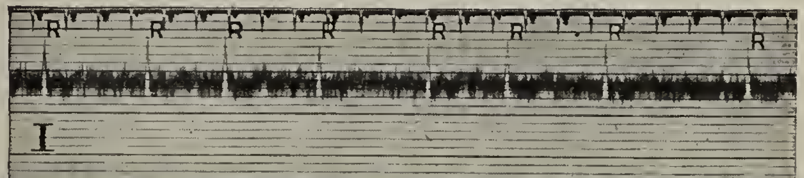

Fig. 11.—Electrocardiogram from a case of auricular flutter. The auriculoventricular rate is sometimes 2:1, at others 3:1, and at others again 4:1. The response of the ventricle to auricular contraction being at irregular intervals, there is irregularity of the ventricular rhythm.

Auricular flutter.—In most cases of auricular flutter there is a constant and uniform ratio between the auricular and ventricular rate, so that the rhythm of the arterial pulse is regular. When, however, as is not infrequently the case, the response of the ventricle to auricular contractions is at irregular intervals, there is irregularity of the pulse rhythm (Fig. 11) it may be even markedly so. In some of these cases the sphygmogram may resemble that in a case of auricular fibrillation; but if a sphygmogram in a case of auricular flutter be carefully studied it will be found that even though the ventricular rhythm is markedly irregular, the pulse beats measure out into groups of equal length, whereas this is never the case in auricular fibrillation. We should consider the possibility of auricular flutter whenever an individual is conscious of a marked increase in the cardiac rate or complains of attacks of palpitation, occurring suddenly and without apparent cause, or suffers from dyspnea on exertion and other indications of cardiac failure coming on rapidly, especially if the rhythm of the pulse is regular. In some cases a correct diagnosis cannot be made with certainty even though the polygraph is employed, an electrocardiographic examination being necessary.

Condition of the vessel wall and the arterial blood pressure.—Lack of space prevents me from dealing with these, except to touch upon a few points. I would first remind you of the importance of examining the walls of the brachial and temporal arteries, as well as that of the radial. Recent investigations have thrown a flood of light upon the pathology of diseases of the vessel wall. This was much needed, as the term arteriosclerosis, which means arterial hardening, has hitherto been applied to at least four different pathological conditions of the vessel wall, namely, 1, chronic inflammation of arteries; 2, degeneration of the intima; 3, degeneration of the middle coat, including Monckeberg's degeneration; and 4, muscular hypertrophy.

In my opinion the term arteriosclerosis should now be discarded. I would refer you to a valuable paper by Dr. Herbert M. Turnbull, in the *Quarterly Journal of Medicine* for April, 1915, and Dr. Theodore Thompson has written a clear account of diseases of the arteries, in view of recent discoveries in their pathology, for a textbook of medicine which I am editing. He classifies diseases of the arteries as follows: 1. Arterial inflammation or arteritis: a, acute; b, chronic. 2. Arterial degeneration: a, of the intima, or atheroma; and b, of the media—1, Monckeberg's degeneration, and 2, fatty degeneration. 3. Arterial hypertrophy. 4. Arterial infiltration, of which the best known variety is amyloid degeneration.

Chronic arteritis is in the vast majority of cases caused by syphilis. The condition primarily affects the arterioles. The aorta and other large elastic arteries are affected secondarily, through the vasa vasorum and their terminations in the external and middle coats. The thickening and thrombosis of the vasa vasorum result in necrosis in the inflamed areas of the media, with consequent weakening of the vessel wall, which may result in circumscribed saccular aneurysm. The large muscular arteries, such as the radials, are only rarely affected by syphilis, so that the latter are almost always not thickened. In chronic arteritis high blood pressure is not common.

With regard to atheroma, syphilis is not a cause. The disease affects the large elastic and muscular arteries. It is usually most marked in the aorta, and as the atheroma may be associated with a similar degeneration of the elastic media a fusiform aneurysm or dilated aorta may result. On the other hand, atheroma does not cause saccular aneurysm. The blood pressure is either normal or only moderately raised. The radial and temporal arteries are frequently affected, becoming irregularly thickened and tortuous, and visible pulsation of these vessels is sometimes to be observed.

In Monckeberg's degeneration the vessels of the lower limbs below the bifurcation of the femoral are most commonly affected and the radial only occasionally. The vessel wall feels like a pipestem, and sometimes crackles when rolled beneath the finger.

Arterial hypertrophy is not caused by syphilis. The muscular arteries, and therefore the radial, are those chiefly affected, the aorta being rarely involved. The vessel wall is felt to be uniformly thickened—the socalled whipcord artery, and this is most evident when the vessel is most contracted. There is usually a considerable rise in the arterial pressure; the systolic reading may reach even 250 mm. or more.

INSPECTION, PALPATION, PERCUSSION AND AUSCULTATION.

May I remind you of a few facts with respect to inspection, palpation, percussion and auscultation. We should be on the lookout for extrinsic causes of displacement of the apex beat and of an increase in its extent. It is also important to remember that the force of the apex beat may be increased by other causes than cardiac hypertrophy, as, for example, in cases in which the chest wall is thin, in retraction of the left lung, when the cardiac action is excited—as during and immediately following muscular exertion or mental excitement, and in irritable heart. In cardiac hypertrophy, the apex beat has a heaving or thrusting character, that is, it is slower and longer than normal, and this sign is the most characteristic feature of hypertrophy. Among other causes of cardiac hypertrophy is an excessive amount of muscular effort, as in athletes and in laborers, in which case it seems clearly established that the hypertrophy may disappear when the cause no longer exists, unless long continued, when it is prone to be followed by dilatation. Diminution or disappearance of the apex beat is, of course, not necessarily indicative of cardiac disease.

In mitral stenosis the apex beat is sometimes in the form of a peculiar sudden tap communicated to the fingers, which is very characteristic. Indrawing of the apex beat, and systolic recession in the intercostal spaces on either side of the sternum, or in the epigastrium, or even of the lateral or posterior walls of the left side of the chest, does not necessarily indicate the existence of chronic adhesive pericarditis. A positive diagnosis of this disease should not be made from the presence of one sign only, except when diastolic rebound or shock exists, after the systolic retraction, and perhaps also in those cases in which systolic recession of the sternum itself exists.

(*To be Concluded*).

Mitral Stenosis*

By SIR JAMES BARR, C.B.E., D.L., M.D., LL.D., F.R.C.P., F.R.S.E.,
London,
Knight of Grace of the Order of the Hospital of St. John of Jerusalem in England.

(*Concluded from Page* 525).

The necessity for this theory seems to have arisen in the minds of certain individuals from the fact that the heart of the tortoise, frog, and other animals, go on beating in a rhythmical manner when removed from the body, and quite free from blood, but I fail to see what that has to do with the more highly specialized function of the mammalian heart. The heart of the tortoise possesses the function of rhythmic contraction in a high degree, and all muscular tissue possesses it to some extent; a clonus can frequently be established in the voluntary muscle. In a venous tracing, which I show, there is a regular series of rhythmic waves during the diastolic periods which might be readily mistaken for auricular beats, but which are really due to the involuntary rhythmic impulses of the hand of the individual who was holding the receiver on the vein; in trying to keep the pressure equal on the vein a regular rhythmic contraction was set up in the hand, and this was overcome by the systole and again reappeared during diastole. Voluntary muscle fibre starts rhythmic contraction under a pressure of six or seven atmospheres, the knee jerk occurs too rapidly to be a reflex, but if you divide the anterior crural nerve, you abolish the knee jerk because you cut off the nervous impulse which maintains the tone of the muscle and tendon, so with the sinor auricular node and the bundle of His, they maintain the tone and nutritive function of the cardiac muscles.

I have often abolished my own pulse and momentarily stopped my heart by tension on my vagi nerves.

I have seen some of Sherrington's experiments on the isolated mamalian heart which he kept beating for hours under the influence of nutritive fluid supplied under a certain pressure through the aorta and coronary arteries. The heart contracted quite rhythmically, and after several systoles there regularly occurred an extra powerful systole of the right ventricle to dispose of the accumulated fluid which had been returned by the cardiac veins to the right auricle, and thus raised the diastolic tension in the right ventricle. If he had depended on any imaginary contraction stimulus to be generated and propagated, rather than on the pressure in the coronary arteries, the heart would have quickly come to a standstill. The living cardiac muscle is irritable and contractile, and can be made to contract by any stimulus; mechanical, chemical, or electrical, but the mammalian heart will only continue to beat rhythmically under the stimulus of a certain diastolic tension in its cavities and in the coronary vessels. The right side of the heart is more excitable than the left and responds to a lower pressure.

CHARACTER OF FIRST SOUND IN MITRAL STENOSIS.

The first sound is unusually loud, clear, sharp, abrupt, and banging or thumping. It may be described as a thud, resembling the accentuated pulmonic second sound, only nearly twice its length. Certain writers, thinking that the mitral valve is not in a condition to generate sound, concluded that this more or less characteristic sound is produced by the tricuspid valve. It would have been well if they had made certain of their premises before arriving at such a hasty generalization. The valve segments are usually in a good condition for generating sound. From the insertion of the chordæ tendineæ over the greater part of the cusps often the whole valve is readily rendered taut with the exception of the thickened and rigid orifice which may permit of free regurgitation. In many cases the valve is so puckered and contracted as merely to form a transverse septum, and in such cases the booming first sound is wanting. When the first sound is duplicated, the first clear, short and sharp element of tricuspid origin is very different from the loud booming first sound heard during the quick action of the same heart. The character of the murmur also affords valuable evidence as to the nature of the segments and the orifice. When the orifice is rough and thick, and the auricular contraction vigorous, you may get a rough purring presystolic thrill at the apex.

THE PULSE.

The pulse is variable. When the compensation of the right ventricle is well maintained, then the pulse is infrequent, slow, small and firm, and fairly regular. When the mitral orifice is much contracted it becomes small, infrequent, weak and irregular, both in force and rhythm, with numerous interpolated systoles. When the right ventricle is much dilated, failing in power and free regurgitation through the tricuspid orifice, then the pulse becomes frequent, quick, small, weak and very irregular in force and rhythm. Interpolated pulsations in the downstroke of the sphygmogram are present in all cases of marked stenosis.

These pulsations represent systoles and never occur before the aortic notch in the primary or subsequent pulsations. The left ventricle contracts on a small quantity of blood which may be barely sufficient to raise the aortic valve, thus producing a very abortive pulsation in the down stroke, or it may be enough to raise the lever of the sphygmograph to its normal height and maintain the ordinary pressure in the arteries. You may have even five or six of these pulsations recorded in the sphygmogram before the lever reaches the base line. At other times the beats may be perfectly uniform and regular for a long period.

CONDITION OF THE LUNGS.

As a result of the chronic overloading, with heightened pressure in the pulmonary circuit, we get increased cell proliferation and diapedesis of the blood corpuscles, giving rise to the condition termed brown induration. In some severe cases the lung tissue becomes quite tough and leathery.

---

*Delivered before the Birkenhead Medical Society, February 9, 1923.

There is also usually bronchial catarrh, and not infrequently hemoptysis. These lung changes give rise eventually to complementary emphysema. The lung symptoms frequently become so prominent as to obtrude themselves on the attention, and obscure the underlying and primary mitral affection.

CONGESTION AND COLLAPSE OF PULMONIC LOBULES.

In the majority of cases of mitral stenosis, if you carefully percuss the back of the chest, especially after the patient has been for some time in the dorsal decubitus, you will find small, circular, and oval areas from about the size of a shilling to that of a crown piece, of comparative dulness. Over these areas the vesicular murmur is defective, the breath sounds rather harsh and slightly tubular, and frequently inspiration is accompanied by a few crepitant râles, and the heart sounds are often clearly conveyed. These little areas of dulness arise from congestion in the pulmonic vessels, some of the aerating space is not required and the air cells are encroached on by the overloaded intrapulmonary vascular cavity. The dullness is never absolute, and the areas are apt to vary from day to day, some clearing up, and others becoming established; they clear up when the patient is moving about, taking deep inspirations, and when friction has been applied to the back. This sign I discovered over forty years ago, and it is one to which I attach considerable importance. The percussion note is only relatively dull, and it is best elicited by delicate percussion; there should be no interference with the vibration of the chest walls.

THE LIVER AND SPLEEN.

The liver is passively congested, especially when there is failure of the right ventricle, and the whole venous system is engorged. The hepatic dulness may extend below the level of the umbilicus, but the spleen is not usually much enlarged. You get the large nutmeg liver.

THE VEINS OF THE NECK.

There is frequently visible pulsation in the veins of the neck, especially when the patient is recumbent; and this may be either auricular or ventricular in rhythm, or both. In tricuspid stenosis the tension in the veins of the neck is much higher than in mitral stenosis alone. In tricuspid stenosis the veins of the heart are much dilated, and those in the substance of the ventricles become like large sinuses.

DROPSY.

Dropsy does not occur until there is failure of the right ventricle, and, unlike that in mitral regurgitation, it frequently begins as an ascites. When it starts in the lower extremities it is due to failure in the left ventricle with fall in the arterial blood pressure rather than to any venous engorgement. Patients suffering from tricuspid stenosis are particularly liable to hydrothrax when dropsy sets in, owing to the obstruction to the vena azygos.

THE SIZE OF THE ORIFICE.

I am in the habit of weighing all the factors in each case, and then mentally estimating the size of the orifice. Usually at the autopsy my estimates are pretty near the mark. The estimated measurements which I generally employ are the size of a lead pencil, the tip of my little finger, my little ring, middle or forefinger, my thumb, or two fingers.

THROMBOSIS AND EMBOLISM.

Thrombi are not infrequently formed in the left auricle, and are readily carried to the brain, spleen, or kidneys. The left middle cerebral artery is a common site of a plug, and then we get aphasia and right hemiplegia. The usually soft and unorganized nature of the embolus renders treatment successful. All lime salts should be removed from the diet, decalcifying agents and strong ammonia freely used.

THE LIME SALTS.

The calcium ions are usually in excess in the blood and in the muscular tissue, largely owing to milk forming a stable article of diet. It is unfortunate that the ideas of a large number of medical men as to suitable diets for invalids should be restricted to milk and the numerous abominable milk foods found on the market.

In fact, some men's ideas are so fixed that you might almost think they were set in plaster of Paris. For the brains of such I would like to prescribe a long course of decalcification. The calcium ions, in my opinion, largely contribute to the evolution of mitral stenosis; they raise the blood pressure by increasing the tone and contraction of the smaller arteries, and by augmenting the viscosity of the blood. At one time I thought the heightened arterial blood pressure was due to arteriolar contraction, but I am now quite willing to give a fair share of the increase to the viscosity of the blood, as I find that the arterial blood pressure can be rapidly and permanently lowered by the free use of decalcifying agents. As the left ventricle has more work to do and has more muscular tissue than the right, it gets a larger supply of lime; its muscular tissue and the musculi papillares get hypertrophied. The violent collision of the mitral cusps leads to cell proliferation, and the large supply of calcium ions contributes in no small measure to the formation of fibrous tissue, and the cementing together of the edges of the valve. When patches of atheroma have taken place anywhere, the abundance of lime salts are readily deposited in the form of calcium soaps.

The calcium ions increase the force of the muscular contraction but diminish muscular irritability; hence the left ventricle often becomes much less responsive than the right, and in this way the calcium ions contribute to the production of the peculiar cardiac rhythm which I have before described. The conclusion of Loeb as to the effect of various ions in muscular contraction are given by Wenckbach as follows:

"1. There are certain ions—for example, sodium chloride, lithium, barium, iodine, and others—which (in solution under a pressure of 4.01 atmospheres) are capable of producing rhythmical contractions in muscles. These ions do not produce such contractions by increasing excitability, because, 1, the contractions continue when the excitability is diminished; and, 2, they do not take place in solutions of nonconductors (for example, glycerine, sugar) at the same osmotic pressure, even when the excitability is normal. It is more natural to think that these contractions are due to definite chemical combinations which these ions form in the muscle.

"2. There are ions which inhibit the rhythmical contraction of normal muscle fibres—for example, calcium, potassium, bismuth, barium. The inhibitory action of calcium, potassium, and probably of all the other ions mentioned here, does not depend on a reduction of the excitability. For on adding a little calcium chloride to some physiological salt solution the contractions are inhibited, while the excitability of the muscle is less impaired and lasts longer than it does in physiological salt solution, when the rhythmical contractions occur. It is more natural to think that the chemical combination which the ions calcium and potassium form in the muscle renders its rhythmical contractions more difficult or impossible.

"3. Hydroxyl or hydrogen ions accelerate the production of rhythmical contractions when they are added in sufficient dilution to solutions of the ions that excite contractions, as enumerated in I. But when they are put into solutions of nonconductors or inhibitory ions they do not have the same effect. They have, therefore, a catalytic action in the production of rhythmical contractions, but are unable of themselves to produce them.

"4. From the very scanty material that is yet available it seems that only ions, and not nonconductors, have the power of setting up rhythmical contractions in voluntary muscle.

"5. The laws regulating the periodical action of the ventricle appear to be similar to those that have been given here for striated muscle.

"6. In all experiments that have been described here it is the muscle substance itself that sets up this rhythmical action, since periodic contractions cannot be started from either the nerves or spinal cord through the solutions mentioned in I."

The human heart requires much less pressure than that stated by Loeb for involuntary muscle to maintain its rhythmic contraction. The ordinary atmospheric pressure or less is sufficient for the right auricle, a little more than an atmosphere for the right ventricle, perhaps a little more still for the left auricle, and often considerably more for the left ventricle. Large hypertrophied and degenerate hearts require high diastolic pressure to maintain their rhythmic contraction; hence in such cases it is not wise to attempt to reduce the arterial blood pressure very low, because if syncope does occur it is difficult to get sufficient pressure up to start the heart again. The actions of calcium and of potassium, stated by Loeb to be inhibitory agents, are scarcely comparable, as the former increases the force of the muscular contraction and delays dilatation, while the latter has a paralyzing effect on contraction, but hastens dilatation. Sydney Ringer long ago showed that the salts of calcium and potassium were antagonistic both in physiological and toxic doses, but in this antagonism their actions were complementary in maintaining the rhythmic contractions of the heart. The high tension in the auricles often sets up auricular fibrillation, or flutter and in such cases agents which lessen the irritability of the cardiac muscle, such as calcium and digitalis, should be freely used.

PREVENTION AND TREATMENT.

As mitral stenosis is usually a sequela of acute rheumatism it is with the prevention of that disease that we should begin. Children with any hereditary tendency to rheumatism should be protected against the vicissitudes of climate and should be encouraged to live a healthy, active life. Those subject to adenoids and large tonsils are specially liable to this disease; these affections are due to defective action of the thyroid gland which in turn is associated with a deficient supply of iodine and an excessive supply of lime. Milk is an excellent diet for infants, but when they have got their teeth a more varied diet should be substituted. Adenoids and enlarged tonsils are easily prevented by giving children small doses of iodine and if necessary also thyroid. The thyroid gland is the natural storehouse for iodine and this should not be replaced by calcium. When the thyroid is properly functioning an immunity is established against these diseases. When rheumatism has not been prevented then it should be treated in the usual way with salicylates and alkalies, but in dealing with it and any subsequent heart affection, diet and hygienic measures are of great importance.

DIET.

In rheumatic fever there is a marked increase in the formation of sarcolactic acid, and all the excretions are acid; I therefore think it advisable to omit all foods, such as starch and milk which give rise to the formation of lactic acid in the digestive tract. There is also a great tendency to the formation of fibrin, hence everything containing lime, such as milk, and all preparations of milk, cheese, gelatine, and animal jellies should be strictly interdicted. Lime also raises the blood pressure and so increases the strain on the valves. I know that I am here running counter to the general advice of the profession, as with most medical men milk is their sheet anchor in their diet for this disease, but I condemned it in 1886 and I have consistently done so ever since. A great many medical men are like the Yankee who did not know anything about measles but was death upon fits, so they make no attempt to prevent the rheumatism, or endocarditis and pericarditis, but when the latter occur they are all alert and quite prepared to give you a learned disquisition on the treatment of these two complications.

One of the recent evolutions in the treatment of pericarditis is to wait till there are some recent adhesions and then start with injections of fibrolysin—without any convincing proof that it is able to resolve even recent scar tissue. This would be really amusing if it were not serious. Personally I prefer to prevent the adhesions by cutting the lime salts out of the diet and making free use of decalcifying agents. Milk should not only be interdicted in acute rheumatism, but also in the subsequent treatment of the heart lesions. An excellent diet for rheumatic fever consists of plenty of hot water, minced meat and poached egg, pounded chicken, steamed sole and other nitrogenous articles of diet. If any carbohydrate be required, well boiled porridge may be given, the silicates in the oatmeal have a decalcifying effect. I am also very fond of syrup of glucose which is palatable when administered with infusion of orange. This, unlike cane, and milk sugar, does not readily undergo lactic acid fermentation. Oranges and lemons may be freely used. When the rheumatic attack is over the diet may be more varied, there may be allowed a fair amount of farinaceous food, and plenty of fruit and vegetables, but milk should still be eliminated.

There are two classes of patients in whom you will find mitral stenosis, the fat, flabby, lethargic, and somewhat phlegmatic individual, who likes her food and does not care for much exercise, and on the other hand the spare, active, rather neurotic individual who does not overindulge in the good things of this life; this latter class wears much better, and this knowledge should help you in directing your diet, which should be light and nutritious with a fair allowance of meat, fruit, and vegetables, and not much starchy food. The food should be merely sufficient in quality and quantity to maintain healthy nutrition, if the patient is laying on fat the food is too abundant. I am in the habit of advising these patients to drink as little fluid as possible, never more than two pints a day, and if the tissues be at all flabby, or there be any venous turgescence, I frequently reduce them to half this amount. All fluids drunk have to pass through the right side of the heart before they are excreted (except what is carried off by purgation), and any excessive amount only handicaps it without producing any benefit. I know that some physicians like to drench their patients with the view of washing away effete products, but it is a much wiser plan to keep the patient on a light, dry diet, and not produce more effete products than can be excreted without flushing. The regular use of all alcoholic drinks should be strictly interdicted. Tea and coffee with cream may be left to the discretion of the patient, except so far as quantity of fluid is concerned. Tobacco should be forbidden. If there be any tendency to edema the salt should be cut down.

HYGIENIC.

During the endocarditis there should be prolonged rest in bed, and the blood pressure kept as low as possible. When mitral stenosis is more or less established a moderate amount of exercise is highly beneficial. The mode of life should be prophylactic against a development of attacks of rheumatism. The patient should be warmly clothed with flannel next the skin, and he should avoid all vicissitudes of climate. When at any time the feet are damp or the body wet and chilled, the clothing should be changed and the surface circulation reestablished as quickly as possible. The action of the skin should be maintained, and for this purpose daily ablutions are necessary. A morning bath at a temperature from 60° to 90° F., according to the susceptibility of the patient, with coarse friction afterwards, will be found very advantageous. The combustion within the system should be as thorough as possible, and with this end in view the patient should avoid all close, heated atmospheres, and live as much as possible in the open air. A warm dry climate is the best. He should not live at too great an elevation from the sea level so as to obviate the effects of a rarefied atmosphere, which leads to pulmonary congestion, and further tasks the already overworked right ventricle. The life should be at a low level, not merely so far as the earth's surface is concerned, but in every other respect, and free from all mental worry and care. The patient should be enjoined to pursue the even tenor of his way in a happy and contented frame of mind, and simple pleasureable emotions should not be forbidden. Marriage cannot be recommended, and a timely counsel against maternity is advisable.

Short of actual fatigue, a fair amount of exercise, even to the extent of hill climbing, will prove highly beneficial, by favoring the circulation, increasing the combustion, and improving the general nutrition. The skeletal muscles contain about a fourth of the whole blood of the body; and exercise greatly increases the circulation through them and so increases the capillary area. On the other hand, if they are not used they require little nutrition, comparatively little blood passes through them, as it tends to flow in the direction of least resistance, thus the capillary area is diminished, and the general arterial tension raised. When, however, any indication of failure of compensation in the right side of the heart occurs, there must be no fashionable treatment by graduated exercise on a mountain side, but the excellent old-fashioned restorative of rest in bed must be at once adopted. If the disease be in an early stage, a few days' rest, a dry diet, and a cholagogue cathartic may be all that are required to restore the *statu quo ante.* If a long stay in bed be deemed advisable, massage should be substituted for muscular exercise.

MEDICINAL.

In the early stages of mitral stenosis the cardiac balance is usually well maintained, and drugs are unnecessary except to regulate the blood pressure for which purpose at this stage decalcifying agents, and moderate catharsis with small doses of calomel, colocynth or salines answer best. When the heart's action is labored and the pulse rather frequent I am very fond of small doses of pilocarpine on account of its stimulating effect on the vagi nerves. I frequently combine it with phosphoric acid and small doses of strychnine or the compound syrup of the hypophosphites. If the thyroid gland be inactive then small doses of iodine and thyroid will prove beneficial. You must not carry your decalcifying process too far as free calcium ions are necessary for muscular contraction and for life. In a later stage the constant high intrapulmonic tension leads to degeneration of the pulmonary vessels, and you not infrequently get a free hemoptysis, which in this case is the best form of blood letting and should not be too quickly checked. In 1886 I condemned the use of all astringents in such cases and strongly advocated the employment of nitroglycerine and atropine. When you wish to clear out any stagnant blood in the air cells turpentine is the best remedy.

If there be any thrombosis or embolism decalcifying agents, such as phosphoric and citric acids, their soluble salts should be freely used. In cases of cardiac thrombosis and pulmonic embolism where the symptoms are very urgent, strong ammonia should be freely used. A mixture of three minims each of liquor ammonia fort, and spiritus chloroformi in a wineglassful of barley water every hour, is an effective remedy.

The chronic engorgement of the lungs leads to bronchial secretion, and brown induration of the lungs with more or less destruction of lung tissue and complementary empsysema. These conditions are best obviated and relieved by a light, dry diet, a dry climate, moderate hill climbing, and little fluids. Also by laxatives, strychnine, nitroglycerine and atropine which are about the best general remedies in mitral stenosis. Cardiac tonics such as digitalis, strophanthus, squills, caffeine, and others, should only be used when there is cardiac failure, and their use should be discontinued when they have served their purpose.

Actinomycosis of the Lungs Simulating Tuberculosis

By HERMAN BESSER, M.D.,
New York,
Chief of Staff, X Ray Department, Jewish Memorial Hospital; Attending Röntgenologist, Lloyd's Hospital.

The clinical and physical signs of pulmonary actinomycosis cannot be differentiated from tuberculosis. The disease begins with a gradual onset. A cough develops, accompanied by expectoration of a yellowish, white sputum. There is an afternoon rise of temperature and night sweats soon follow. There is progressive loss of weight, accompanied by malaise and debility.

Pulmonary actinomycosis differs from tuberculosis in its morbid anatomy in that the disease spreads by continuity. In the early period of infection the disease manifests itself in the formation of small miliary tubercles which later coalesce and form large masses. They take on the appearance of a malignant growth of the lungs, and unlike tuberculosis, ignore anatomical boundaries. The infection spreads to the pleural sacs, causing an adhesion between both sacs and finally rupturing through the intercostal spaces and involving the rib structure. Necrosis of the rib develops and resembles a caries of the bone.

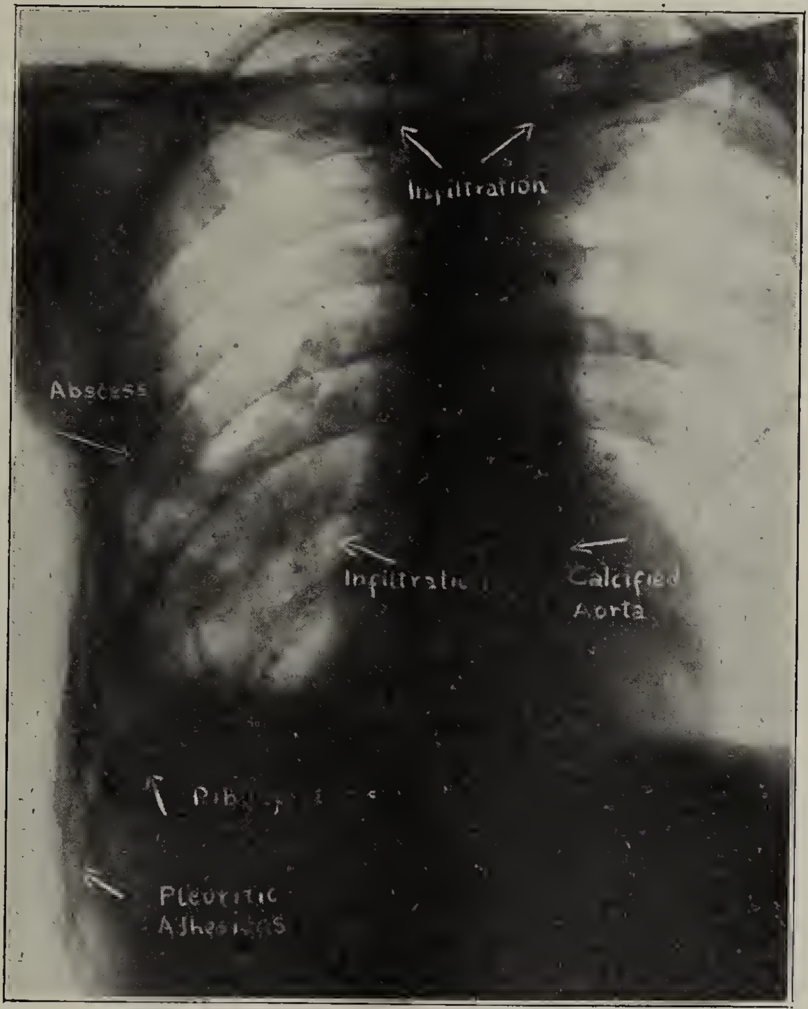

Fig. 1.—X ray photograph showing involvement of the lungs and suppurative process of the ribs in Case I.

The following case was referred to me for x ray diagnosis of presumptive tuberculosis of the lungs.

Case I.—The patient, Mr. A., aged forty-five years, first noticed his symptoms eight months previously. He complained of cough and pains on the right side, accompanied by progressive loss of weight and general weakness. His appetite was poor. The condition becoming worse, he was sent to the hospital with the presumptive diagnosis of tuberculosis and remained in bed for a month. Physical examination revealed marked dullness of the middle lobe of the right lung, extending towards the base. Breath sounds were harsh and numerous râles, both fine and gross, were heard over the dull area. Sputum examination made on three separate occasions showed the absence of tubercle bacilli. The Wassermann test was negative.

The patient was extremely emaciated, the skin had a sallow appearance, and there were numerous furuncles scattered over the chest. Respirations were increased and shallow.

Fluoroscopic examination revealed the following: The right lung showed decreased illumination of the middle and lower lobes. The apices failed to illuminate on deep inspiration. The upper right intercostal spaces showed extreme narrowing. The left chest showed compensatory emphysema. The right costophrenic and cardiophrenic sulci were obliterated. There was no fluid in either chest. The heart was of the pendulum type and not enlarged.

A radiographic examination made in the vertical position at two meters' distance, disclosed well marked parenchymatous infiltration of the lower and upper part of the middle lobe on the right side. There was also infiltration of the right apex. The left lung showed a small infiltrated area near the hilus. The aorta showed evidence of calcareous degeneration. On the right side above the nipple line, there was an oval radiolucent shadow. This shadow indicated an abscess about the size of a half dollar. The ninth and tenth ribs near their angles showed evidence of necrosis. The diagnosis was active actinomycosis. Clinical and physical findings pointed to a frank, active tuberculosis, but the marked involvement of the lungs and the suppurative process of the ribs, as shown by the x ray, pointed to actinomycosis. This diagnosis was substantiated later by the appearance of abscesses on the chest and back.

In examining chests with pulmonary symptoms the possibility of active actinomycosis should be taken into consideration, for this disease is not as uncommon as formerly believed. No doubt failure of recognition of this disease, which is almost invariably fatal and which passes for tuberculosis, accounts for the meagre report of cases in this country. Actinomycosis is common in Europe. The infection is believed to be acquired by those handling straw and vegetable products, as the disease is widespread among cattle and domestic animals.

The case here reported is the second within six months that has been referred to me for x ray diagnosis for presumptive tuberculosis in which the ray fungus was the offending organism.

50 West Fifty-Fifth Street.

A Message to the Laity*

By J. W. KENNEDY, M.D., F.A.C.S.,

Philadelphia.

It is inconsistent with good religion to know that a profession engaged in the lifesaving service should have its privileges so intercepted by a legislative enactment that mortality in many of the death dealing conditions is doubled and trebled. I cannot imagine that a wise Creator brought us into this world and then intended we should have our rights to expand denied us, and especially must this be true of a lifesaving service.

The time has come when we as a profession must no longer tell our troubles to each other, but we must reach the great legislative bodies of our country. It is they who are utterly ignorant of our rights, privileges, wisdom and the magnificent power of our profession.

I cannot conceive of so deliberate a wrongdoing of the great legislative minds of our country who by passing laws which are obstructive to our progress, deliberately take life. They will not assume this responsibility and possibly we alone know their guilt. It is therefore our duty to take in council the constructive, influential and intelligent nonmedical men of our country and tell them our troubles; tell them the death rate of our privileged profession and what it really is today as a result of permitting irregular men to practise.

We must give these gentlemen something tangible to figure from; many of them deal in abstract facts. It does not mean enough to them to hear that our regular profession is an advanced one and that the many irregular pathies which have come forth in recent years are robbing us of our legitimate privileges. A statement like this is dismissed as a mere difference of opinion, as one expressed by our profession who would naturally favor our own. It does not have a serious ring. We must give the authorities who are controlling the legislative destinies of our country facts, clear cut, unmistakable facts, facts which have been founded upon the greatest of all tragedies, death. It is my opinion we of our profession will be forced to bring this question of responsibility for death intimately into their lives; and right at this place I want to say in confirmation of this statement, I have signed many death certificates which should have been signed by the legislators who permitted the irregular to place his sign in the neighborhood of the unfortunate and misguided patients.

Admitting that the laity are ignorant of the real differences in ability of regular and irregular professions (and they are entitled to this courteous distinction), how can we prove our rights to supremacy? This is exactly what the near future must bring about. As our profession stands today, humble yet supreme, from a legislative viewpoint there can be no abuse in all American law so reprehensible as that which permits two or more standards of medical education. We must get these facts to the President of the United States, to Congress and to all of our legislative bodies.

I cannot conceive of more supreme ignorance than that which is made manifest by the enactment of certain legislative requirements necessitating the highest possible educational qualities for our profession and then permitting men of practically no preliminary or scientific preparation to practice the art of healing, as our competitors.

Privileged results must be contrasted by definite figures with those which exist as practised by a crippled profession. The causes of the crippled profession must be defined as to individual responsibility and after all individual responsibility for good or bad is that definite something we must know. Throughout my professional life I have seen the great virtue and strength of individual responsibility. It is an awful burden to carry, often a tragedy, but without it the physician is a weak, soulless and dangerous man. I cannot help but feel that we must demand that our profession be put upon trial, we must demand investigation. The relative merits of our profession must be pitted against those of all irregular pathies, since these pathies have been recognized by legislative enactment.

Permit me to engage in a little trial: suppose we had a committee of three men of the calibre and distinction of Messrs. Wilson, Hughes and Taft who have been appointed to investigate the relative merits of our profession as compared with any of the irregular pathies which may have been recognized by law. It is only fair to suppose that the gentlemen composing this committee would reason from the common fitness of things and therefore know that there can be but one supreme standard of medical education and that would be the highest within the gift of man. These gentlemen would further know that any remedial agent or scientific fact would be best known by that profession which had exacted of its members the greatest degree of preparation in their scientific education. The intelligence of this committee therefore would recognize the single high standard of medicine. We are now ready for our trial and from our fruits we shall ask to be judged.

It seems to me before our trial begins the conclusion is definitely drawn, probably a shrewd lawyer at this point would ask the judge to withdraw the case in favor of the defendant. Is it really necessary for us to bring in the evidence of relative accomplishments? In the great science of preventive medicine, has anything been done other than by our regular profession? There is no work in general science, commerce or the professions which in any way measures up from the point of view of value to humanity (and certainly this is the greatest of all values) than that of preventive medicine. It is not even necessary to speak of the accomplishments of surgery of the regular profession, there is certainly no competition here with other pathies; it is lacking in dignity to bring the accomplishments of our regular profession into competition of relative merits with the many pathies which may constitute the irregular schools of our country, but, legislators humiliate us and it must come to a showdown because a single high standard of medicine must be the outcome of the reasoning processes of thinking men.

---

*Presented before the Schuylkill County Medical Society.

The surgical profession is much indebted to Dr. Franklin Martin for the organization of the College of Surgeons of North America, which is our greatest effort in this country to raise the standards of surgery. A great and permanent work has been accomplished, but this powerful organization will be hopelessly crippled as long as a single institution in this country or the world for that matter, graduates an irregular practitioner of any kind. How purposeless and discouraging is it to strengthen the front door of our profession by scientific advancement if the back door is left open for the irregular to enter. Scientific men are busy with their important professional work and are too tolerant of the irregular who is taking from him the accomplishments of his scientific investigations. We do not sufficiently stand upon our dignity, the majesty of which must be measured by the salvation of life. I question if any member of our profession should accept any state health position as long as there is a single law in that state which in any way recognizes other than the regular school of medicine. I certainly would not. As an abdominal surgeon I know that over ninety per cent. of the deaths which occur in my specialty come from human errors and that a reprehensible proportion of this death rate may be laid at the door of our state legislatures.

I have mentioned Dr. Martin on account of his results from organization and standardization. Suppose he were a cabinet member at Washington as Secretary of Health (such secretary should have existed long ago) and in the performance of his duties as Secretary of Health he declared that no progress can be accomplished in the American Health Department until a single high standard of medical education is recognized; the next question which would naturally be asked by the President of the United States is: What is this standard of medical education for which the secretary has asked? He would then appoint a committee to investigate. This is where the committee of gentlemen of distinction which I early mentioned can perform the most deserved and humane services to my knowledge. There could be but one outcome to such investigation and that would be the exclusive recognition of our regular profession. It is more than likely during this investigation some members of this committee will say, "After all, Dr. So and So (naming some irregular) is not half a bad fellow, quite harmless, he manipulated my vertebræ last Wednesday and I feel better for it." It will then be the golden opportunity for some member of our profession to say "Yes, he also manipulated the vertebræ last Wednesday of one of my patients who had a perforated appendix and today I signed the death certificate."

Gentlemen, this seems to be simple, childish talk, almost playing marbles, but I want to say to you that we must get down on our knees and play marbles with the laity. They are not understanding us, more yet, they are not concerned. My message to you is, each of us must take into his confidence the most influential layman of our acquaintance, tell him these facts, show him the urgent need of proper legislation to protect our rights and permit us to follow our practice. It will be necessary in our arguments to the laity to deal in some detail, to simply say the accomplishments of preventive medicine has been magnificent is not sufficient. Remember we are on trial, therefore it will be necessary to tell them something about Jenner, the father of preventive medicine; of what the mortality of smallpox was before and after vaccination and what Jenner's great discovery accomplished. Give them the figures.

Tell them what this same principle has done in diphtheria in the salvation of millions of lives of their children. Give them more figures.

Tell them how our profession dug the Panama Canal and that the French did not fail in their engineering to negotiate this canal but that yellow fever stopped their work; tell them the story of the scientific and courageous medical men who lost their lives but demonstrated the fact that a certain variety of mosquito spread the plague of yellow fever; give them more figures and explain that this is another great step in preventive medicine. Tell them the same story about malarial fever, with more figures. You are dealing with business men, you must give them figures. Ask them what profession is guarding at this very hour every mile of coast which our country possesses to see that the great plagues are kept from us, and, if you please, ask them if any other pathy has done or is doing anything in this greatest of all work.

If this has not made an indelible impression upon them and they say: "Can you not go on with our scientific work and still permit the irregular to exist?" Your answer must be: "We can never advance or raise our standards by competing with men of inferior preparation who have no scientific therapeutic facts; they only handicap us in our work."

We must further show the laity the efforts our profession has made in this country to advance and standardize our own profession by closing over sixty per cent. of our medical colleges which could not meet the required standard, and that this has even to a larger per cent. decreased the number of our graduates of regular medicine. This, of course, gives the irregular schools an excellent opportunity to spring up all over our country. One of these institutions, I am informed, graduated more men this year than our combined medical colleges of America. How can the legislators require any degree of standardization of our profession with this damnable state of things existing? Authorities require definite standards of preliminary education, a prescribed course of medical training, a year's internship in certain recognized hospitals and then examination by state boards of examiners for results; do they get them if men of inferior preparation are permitted to practice any kind of medicine? They certainly do not.

A crippled privileged profession is more reprehensible a million times than an ignorant one. I hold American law culpable for many deaths. For the law to require a certain standard of us and then not protect us in such standardization is inconsistent with all the laws of intelligence, is a breach of faith and trust and is a personified exhibition of sheer ignorance.

241 North Eighteenth Street.

Editorial Articles

THE ABOLITION OF COCAINE

The increase of drug addiction has coincided with the increase of restrictive legislation in all directions. The statement is probably true of this country and according to reliable reports is assuredly true of Great Britain. Is it also true that drunkenness has increased in this country of late and that the increase has coincided with the advent and establishment of prohibition? Is it possible that this growth is a symptom of a neurosis known as the "nervousness of suppression?" Whether these statements be wholly or only partially true, the fact remains that drug taking is unduly prevalent in civilized countries. There are some drugs which are peculiarly harmful but which can be obtained with comparative ease because they are largely manufactured on the plea that they are called for in medical practice. One of the most conspicuous and pernicious of these drugs is cocaine, which is manufactured largely presumably on account of its value and employment as a local anesthetic, mainly by dentists. But there have been for some time fairly efficient substitutes which have no action on the central nervous system, to wit, novocaine. Recently, too, a new synthetic product known as butyn has been prepared in Chicago which, according to a statement made by Dr. W. M. Beaumont, in the *British Medical Journal,* January 13, 1923, is most satisfactory as an anesthetic in ophthalmic practice.

The argument advanced by most of those who have made a special study of the drug traffic is that the only sure means of abolishing the traffic in any particular drug is at the source of supply. If a drug is not manufactured, it cannot be disseminated through the world as cocaine is disseminated, and if a drug is not needed in medicine or surgery, as it is now said cocaine is not needed, why manufacture it? It is submitted by those who have had great experience in the drug traffic that the only mode of abolishing the use of cocaine is by international action and, as said before, this is now feasible without detriment to any department of medical or surgical practice. It is absolutely certain that as long as cocaine is manufactured it will be misused in spite of stringent legislation, some of which, like the Harrison Law and the new amendment to the British Drug Act, press hard on medical men. It is argued, therefore, that international action should be taken to end the present manufacture of cocaine in Germany and Switzerland or elsewhere and the cultivation of the coca plant in Peru, Java, Bolivia, and other countries. It is further urged that the best instrument for such action, given an instructed and active public opinion in the various countries concerned, is the opium committee of the League of Nations. Though neither the United States nor Germany is a member of the League, both of these countries are represented on the opium committee.

It is a matter concerning which there is no dispute that cocaine taking is a destructive habit and one which should be abolished if possible. It is also a matter of notorious knowledge that by far the greatest part of the cocaine manufactured is illicitly sold and misused and it has been plainly demonstrated that repressive or restrictive legislation is of little or no use. Therefore, if cocaine is not needed in medicine, surgery or dentistry, it seems that the only way to stop its abuse is to prevent its manufacture and prohibit its cultivation.

International action might prevent its manufacture on a large scale but it is difficult to understand how its cultivation could be prevented. However, the prevention of its manufacture on a large scale would greatly curtail the consumption of a drug which, when it becomes a habit, causes physical deterioration and mental debasement. In any event, the subject is one which should be discussed and freely ventilated in medical and lay journals. Formation of public opinion is a long step towards the doing away with an abuse.

THE EXAMINATION OF THE HEART FOR LIFE INSURANCE

It goes without saying that the condition of the cardiovascular system is of prime importance in the examination of candidates for life insurance. Indeed, it would be correct to state that it is the most important point in such examinations. It therefore follows, as a natural sequence, that accurate diagnosis is essential to the interests of life insurance companies, and it behooves them to have as medical examiners skillful and scientific diagnosticians. Now without unduly impugning the knowledge of the medical profession in regard to the cardiovascular system, it is undoubtedly true that the general practitioner does not, as a rule, possess that special knowledge of the heart which will render his decision final as to abnormalities and diseases of this organ. To become an expert diagnostician in this branch of medicine requires a special aptitude and years of close study. Sir James Mackenzie has taught this truth, and has been the pioneer in modern methods of heart examination. Medical examiners for life insurance companies will freely acknowledge their debt to that great Scotchman, and will no doubt further admit that they have something yet to learn with respect to the accurate diagnosis of cardiovascular diseases or defects.

The paper by Frederick W. Price, M. D., F. R. S. (Edin.), which it has been our privilege to publish, is perhaps one of the most complete ever written on the examination of the heart for life insurance, and while it does not cover the whole subject, it deals lucidly and in easily comprehensible language with the salient points. Perhaps the most instructive part of this paper, to medical examiners, is that which deals with irregular action of the heart, although all the points debated are of the first importance. However, there is no space to even touch on the various matters dealt with and reference will be made only to the remarks of the writer of the article concerning the influence of rheumatic infection of the heart in childhood upon its condition in after life.

Stress is laid on the fact that as yet it is not sufficiently realized how easy it is to overlook a rheumatic infection in childhood and it is pointed out that in trying to elicit such a history it is necessary to bear in mind that cardiac involvement is a much more frequent manifestation of rheumatic infection in children than in adults; it is, at least, as frequent an indication of rheumatic infection as any other condition and should not be regarded as a complication. It may occur in association with arthritis, which in children is usually slight, or in association with the affection confined to the tendons or the fascia in the neighborhood of the joint; in association with subcutaneous nodules, certain exudative erythemata and purpura rheumatica, which are more common manifestations of the rheumatic infection; with chorea, which is a frequent indication, and with tonsillitis which is perhaps more often of rheumatic origin in childhood than in adult life. The heart may be involved in association with an indeterminate febrile attack, or it may be the sole manifestation of rheumatism. Moreover, the point is emphasized that while endocarditis may occur acutely in children, as in adults, it often occurs in a subacute and insidious form, there being not infrequently a total absence of subjective symptoms, or, when symptoms are present they are often masked by other manifestations of the causal infection. In short, it cannot be too strongly emphasized that rheumatism in childhood in one form or another, sometimes undetectable, is a frequent origin of heart disease in adult life, which unfortunately may not manifest itself until years after the primary infection.

Dr. Price's paper is full of useful hints as to how to diagnose, with as fair a degree of accuracy as possible, various types of cardiovascular disease and derangement which can only be detected by one thoroughly versed in the methods initiated and developed by recent investigators in this wide field. This modern teaching is being applied to practical purposes by its followers, and, of course, a good knowledge of up to date methods of correctly diagnosing the numerous phases of heart affections is of supreme importance to those members of the medical profession who are called upon to examine candidates for life insurance. It is essential for prognosis which, as Dr. Price points out, is a most difficult problem, that the diagnosis be as accurate as possible, especially with regard to irregular action of the heart and to cardiac murmurs and their significance.

To recapitulate, it may be stated that the question of medical examination for life insurance is largely concerned with the condition of the heart and it is to the obvious interest of all concerned that those who do this kind of work should be sufficiently skilled to detect the signs of the more common abnormalities of the cardiovascular system and ascribe to them their true significance.

A ZURICH SURGEON OF THE SEVENTEENTH CENTURY

A curious personage certainly was this Zurich surgeon of the Seventeenth Century called by his compatriots the "barber of Thalwil"—*der Thalwyler Schärer.* It is to be recalled that at his epoch, and even for years after, barber and surgeon were coupled together. The greatest surgeons of the time began their career as apprentice barbers—among them Ambroise Paré—and this was the case with Hans Jacob Ammann, belonging to a family of barber surgeons, who was born at Thalwil on the Lake of Zurich, in 1586. When he finally settled in Zurich he acquired a more than local reputation. One of his descendants, Mr. Auguste F. Ammann, has recently told the story of his ancestor and has republished the travels of Hans in the Holy Land, from July, 1612 to September, 1613. These travels crowned long peregrinations in Germany and in French speaking parts now comprised in the Swiss Confederation.

In his youth, Hans Jacob Ammann started on his travels, not merely to see new lands, but to gain knowledge of medicine. At the age of twenty-four he was in Rome and later in Vienna where he remained four years. It was in this city that Ammann met one Negroni, an influential Greek, whom the Emperor had ordered to convey to the Sultan, at Constantinople, certain presents that were exchanged once every three years. Negroni appointed young

Ammann surgeon to the Embassy and after a trip lasting forty-two days, Constantinople was reached. At Constantinople Ammann was seized with the desire to see more and with a Dutch gentleman, an Armenian, some Turkish merchants, and two monks he set out for the Holy Land, by way of Asia Minor, Antiochus and Damascus. He traveled throughout Palestine, remained quite a time in Jerusalem and returned by way of Egypt and Italy.

The account of these travels given in his book *Reiss ins Globte Land,* published in 1618, was so successful that the book went through three editions, while the fourth has recently appeared. The text is keenly interesting. Hans was of an inquiring mind and interested in all things. Unlike the physicians of Molière, his medical kowledge, entirely derived from observation, is based on experience. On the other hand, his long travels cultivated and enriched his mind and his medical talents profited by this as well.

It should be recalled that at this epoch, Europe had still much to learn from the Orient, where the traditions of the Greek and Arabian physicians were being revived. In all countries visited, Ammann studied the medicinal plants and their healing virtues, examined into the sanitary conditions of cities, visited hospitals and the various mineral waters and baths.

Ammann returned to Zurich in 1613, established himself as a surgeon, and soon acquired a large clientele. His original mind and freedom of judgment made him very pleasing. After practising his profession for forty years, Ammann decided to return to his native village where he died in 1656 at the ripe age of seventy-two. The *Thalwyler Schärer* was a sage and most of us could profit by his views of life and things.

DR. CONSTANCE E. LONG

The sudden death from influenza pneumonia in New York City not long ago of Dr. Constance E. Long, of London, was a great shock to her patients and friends, both in this country and abroad. At the time, Doctor Long was planning to leave for England, but to return next fall to this country with a view to settling permanently in New York.

Doctor Long came from a large, noncomformist Puritan family living near Reading, England. Doctor Crichton-Miller, writing in the *British Medical Journal* says in this connection: "Brought up as she had been in this tradition . . . she had no doubt many complexes to submit to analytical treatment; but she also had that heroic urge towards the 'better than what is' that made her contribution to her day such a notable one." She commenced the study of medicine with the idea of becoming a medical missionary, but her health, always far from robust, prevented her from ever being able to undertake foreign service. After obtaining her medical degree in 1896, she held various medical posts, among them those of resident medical officer at several institutions, and later that of clinical assistant at the New Hospital for Women, the Royal Free Hospital, and Evelina Hospital. In addition, she established a successful practice, and gave courses of lectures on medical subjects in colleges and other institutions of learning. She held the office of president of the Association of Registered Medical Women, and was a member of the Insurance Acts Committee of the British Medical Association. In 1919, when the International Conference of Women Physicians was held in New York City, she was one of three British medical women chosen to attend the conference, and delivered one of the most interesting and significant addresses of the session. She was one of the founders of the British Psychomedical Society, and at the time of her death was a member of the Committee of the Medical Section of the British Psychological Society.

During her practice, Doctor Long had noticed the frequency with which the functional factor affects disease conditions, and this led her to the study of suggestion. Under the influence of Dr. Lloyd Tuckey, she became a successful practitioner of hypnotic suggestion. She was too progressive, however, to remain satisfied with suggestive therapeutics, so, in 1914, she went to Zurich, where she studied analytical psychology under Jung, and became afterward the first exponent in England of his views and practice of psychoanalysis, which had heretofore been strictly along the lines laid down by Freud and his followers. She translated into English Jung's *Collected Papers on Analytical Psychology,* was one of the editors of the *British Journal of Psychology,* and the writer of numerous articles on psychological subjects. Some of these were collected and published in her book, *The Psychology of Phantasy,* which is a simple but most interesting exposition of the principles of psychoanalysis as laid down and practised by the Zurich school.

The British medical journals have published numerous tributes to the value of Doctor Long's work. The *Lancet* says: "Doctor Long's death removes a medical woman whose breadth of outlook and wide knowledge made her well known and respected by her professional colleagues. Doctor Jung regarded her as an honored collaborator." Dr. James Young writes: "By her death, the profession loses one who strove always to further the interests of medical science, and who bravely fulfilled the arduous function of pioneer in its most difficult and exacting department—that of medical psychology. She will be mourned by all those, friends and patients alike, who knew her for what she was—a woman of kindly and sympathetic understanding who maintained an untiring devotion to duty in the teeth of the adversities of ill health and of those incidental to all attempts to broaden the basis of knowledge in any branch of human thought." Dr. H. Crichton-Miller writes in the *British Medical Journal*: "By the death of Dr. Constance Long, the profession loses a notable pioneer and a somewhat remarkable figure. . . . Those who admired her most will agree that the driving factors in her makeup were unfailing generosity and sincerity. Nobody could ever imagine that Doctor Long was acting from any ulterior or selfish motive. While she talked and wrote a great deal about that spiritual freedom which analytical treatment is intended to procure, her life showed forth much more evidently a selflessness attained in a much more old-fashioned school. . . . In all her offices her place will no doubt be filled, but her place will not readily be filled in the hearts of many friends and patients, who had learned to appreciate her wisdom, her integrity, and her sympathy."

HIRSUTES

There is always enough agitation on the surface of medicine, but its real progress is painfully slow. Particularly does this seem the case with reference to diseases of the skin. This composite organ we have immediately under our eye and hand, and yet it is safe to say that we know less about it, physiologically and pathologically, than about any important structure in the body. The textbooks on skin diseases, save on the mere side of description of lesions, are most vague and dismal pieces of literature, and, when it comes to treatment and prophylaxis, we are not greatly refreshed.

It is quite true that the skin is most intimately mixed up with the body which it covers, and reflects, to a large extent, what is going on beneath, and perhaps the skin man's retort to any critcism would be that he awaits more information about these internal organs. Still it would seem that only within the past few months has any attempt been made to find out definitely about such simple, but very important matters, as whether shaving; or the use of grease, or exposure to sunlight, affects the growth of hair. The answer of these experiments contradicts common teaching. These conditions do not increase growth.

The face and its condition, or complexion, are of more importance to man, or at any rate to woman, than any part of the body, and there is, probably, more suffering (mental, but none the less real) on account of facial blemishes and, in particular, superfluous hair, than from all other skin diseases put together. Electrolysis has been recommended above all other means of treatment, but it is expensive, painful, and often well nigh endless, as it must be repeated time and again, because follicles are missed or because of new growth due to stimulation.

Women have had an aversion to the use of a razor, an aversion due probably, to a large extent, to the popular notion that the cutting of hair causes it to grow faster and become stiff. It is to be hoped that the results of the experiments referred to will help in encouraging a further use of this weapon. No one seems to have investigated the question of whether there is a stimulation to growth from the use of chemical depilatories. These are in wide use under one name or another, and one prominent dermatologist has dared to say that they are not so bad as is often made out. Some dermatologist will do humanity a world of good by laying his finger on the cause of hirsutes and by discovering a means of its prevention or actual cure.

PROTECTION

The physician is notorious as a poor business man. He spends his life in an elaborate preparation for his work, ministers to the sick, prolongs and protects human life to the best of his power and usually ends by neglecting his own health and in turn the welfare of his family. His enthusiasm and earnestness carry him away from his own security. His main capital is his skill and personality. Should these in any way be interfered with he is handicapped much more than most of the men in other professions or those in business.

For these and other reasons he should make some adequate provision for the care of those dependent upon him in the event of any impairment of function due to accident or disease. He should protect himself even as he seeks to protect others. This advice is given from a purely utilitarian point of view. It is not a question of sentiment but rather one of common sense or business.

Just how might he best secure this protection has been studied by certain life insurance organizations. They have devised plans whereby his needs were carefully considered and have perfected systems which are in the nature of business investments which in turn serve to protect him from the many contingencies which he may encounter. The question of this more modern and specialized life insurance for men in the professional ranks is meritorious and should be investigated by all physicians. It is merely a question of fulfilling their duties to themselves.

GYMNASTICS FOR INFANTS

The age of gymnastics probably reached its height in the latter half of the nineteenth century and, fortunately, has been waning. Begun by able enthusiasts who too often made physiology and anatomy to suit their theories, gymnastics became the money making field for sundry charlatans who preached their various systems from the housetops. Probably none of these systems did much harm to adults, but some even went so far as to apply them to the newly born.

So far as we know, no physicians in this country have "taken up" with this attempt at precocious physical development, but within a year two articles have appeared in the medical literature of Central Europe. Possibly the condition of young children in those war drained States has made it seem needful to do something more than let them grow up naturally, but these physicians have made the mistake so common among advocates of physical training, that of putting the cart before the horse, or, in other words, the exhibition of energy before its source. Exercise in children is but the expression of abundant energy, and overflowing energy means plenty of food. Given normal nutrition, a child cannot be prevented from exercising. Moreover, it is far safer to let him choose his exercises for himself. It may be well to pick up and handle a child under one year, but a child of that age needs no special apparatus or exercises for his development.

When it comes to children of school age, they too will exercise if they are well fed and have half a chance, but the last form of exercise we should offer is that of formal gymnastics, and then only as a makeshift. Educators have been, theoretically, believers in Herbert Spencer's *Education,* but they have paid little or no attention, practically, to what he has to say against formal gymnastics. They may do for school children where nothing better can be offered, but certainly they have no place in the nursery, for they are pretty certain to be more harmful than beneficial.

THERAPEUTIC HAND WEAVING

The curative value of working with the hands is receiving constant recognition in the installation of occupation therapy in the increasingly large number of hospitals and other institutions. But there are as yet almost no opportunities for taking advantage of such work outside of institutions. Perhaps the first step to furnish such opportunities has been taken by two young women of this city, Miss Edith Snow and Miss Beatrice Abbott, who have recently opened a studio for the teaching of hand weaving at the Art Centre, 65 East Fifty-sixth Street. Miss Abbott and Miss Snow are members of the American Occupational Therapy Association, and have the endorsement of many well known members of the medical profession. It is desired that pupils work under the direction and with the cooperation of their own physicians. Weaving has been proved to be, in the institutions where it has been tested, one of the two or three crafts most important in occupation therapy. It has several distinct advantages for both doctor and patient. In the first place, it is an interruptible craft, hence the amount of time and concentration to be given by the patient can be regulated by the physician. Then, the process may be either largely mechanical, in which case, the rhythm and exercise gained from manipulating the loom are restful, soothing and beneficial to the patient; or interesting and beautiful effects may be produced, which furnish an immediate incentive to the pupil. Also, the work requires close but not strained attention, and develops patience and initiative. Perhaps the chief curative principle involved is the training of emotional control. The worker must learn to govern, not only his machine and his design, but also himself, if he is to get results; yet this process is neither arduous nor tense. Thus interest, adaptation and habit lead to control.

SPECIAL CLASSES IN ATLANTIC CITY

In a small but most attractive pamphlet of only twenty-four pages, Charles A. Boyer, superintendent of the Atlantic City Public Schools, brings before teachers and the general public valuable information about classes for subnormal children. The pamphlet deals with the organization and management of such classes in the public schools of Atlantic City. These classes were organized before the passage by the New Jersey General Assembly of the law making special classes mandatory, and have now been increased to eight in number. All children are given the Vineland (1919) Binet and Porteus tests. No child with an intelligence quotient above seventy-five, nor with a Binet above ten is admitted. All children are reexamined annually. There is no hard and fast rule about keeping children in special classes. Children who show signs of mental weakness should be examined early in their school life, for when admitted later they have formed already poor work habits, and it is often difficult to arrange a program suited to their ability. In a discussion of the problem of feeblemindedness, four channels of attack are given: 1, education, to develop all that the children have, both physical and mental; 2, legislation, in an attempt to control the mating of individuals in society, so as to insure normal children; 3, segregation, or institutional care; 4, surgery, which, in the male, consists of a ligation and resection of a portion of the vas deferens, and in the female, severing the fallopian tubes. The only true solution of the feebleminded problem is institutional care. These children have no place in a city school system where they come in contact with normal children. The pamphlet has a number of excellent and suggestive illustrations of various phases of the work. It should be of great value to the teacher, nurse, or physician interested in this aspect of medicine and education.

PROPER CREDIT

Dr. Harry R. Litchfield and Dr. Leon H. Dembo, whose article on Clinical Errors in the Diagnosis of Acute Contagious Diseases appeared in the March 7, 1923, issue of the JOURNAL, wish to call attention to the fact that the reference to "pin point pearly white spots occurring occasionally on the congested caruncle on the inner canthus of the eye, two or three days before the morbilliform eruption" was first pointed out to them by Dr. I. H. Goldberger, of New York.

News Items.

Fight Diphtheria in Milk.—A dozen scientists from all parts of the Eastern States are at the Borden plant at Endicott, N. Y., experimenting on methods to eliminate permanently the danger of diphtheria infection from the milk supply of the country.

Dr. Wallace Resigns.—Dr. Charlton Wallace has resigned as surgeon in charge of the Reconstruction Hospital, 100th street and Central Park West. It was learned that the trustees of the hospital had indefinitely postponed the contemplated erection of an eleven story building to cost $1,500,000.

Lorentz on League Board.—The Council of the League of Nations at Geneva has elected the Dutch physicist, Hendrik Lorentz, to membership on the Commission on Intellectual Cooperation. He replaces Professor Albert Einstein, who recently resigned. Dr. Lorentz is a foreign associate member of the French Academy of Sciences, professor of philosophy at Leyden, Holland, and an honorary member of the Royal Institute of London.

Radio Medical Service for Seamen.—Just a year ago the United States Public Health Service announced that it had completed arrangements to expand the medical aid service to American seamen, with which it had first been charged by Congress a century and a quarter ago, by prescribing by radio for any sailor who might be taken ill at sea and who might apply. The diseases and mishaps for which aid has been invoked includes appendicitis, asthma, cramps, diarrhea, earache, eye injuries, heart disease, hernia, hiccoughs, influenza, infected teeth, malaria, opium poisoning, ptomaine poisoning, and swallowing broken glass. Sometimes interchange of several messages was necessary to obtain clear information as to the cause of the trouble.

Medical Health Centre.—The Medical Health Centre for the Treatment and Prevention of Disease, 231 West Fifty-first Street, New York City, is an institution which was founded in order to help those requiring the attention of specialists, who are without the financial means for such care and who do not wish to accept charity treatment. It was established also to supply a central place where the public may go for consultation and then return, if they wish, to their own physicians for treatment. Information about the prevention of diseases is also supplied. The Medical Centre specializes in the treatment and prevention of skin, kidney, bladder, blood, and genitourinary diseases. Other specialties will be added as the institution grows. The work of the centre is carried on purely as a philanthropy. Charges are nominal and the proceeds are used to cover the expenses of maintenance and educational work.

Alpha Omega Alpha to Meet. — Syracuse Chapter of Alpha Omega Alpha will hold its annual public meeting at the First Baptist Church, Syracuse, on Monday evening, May 14, 1923, at 8:30 o'clock. An address entitled Treatment of Chronic Cardiac Diseases will be presented by Dr. H. A. Christian, Hersey professor of the theory and practice of physic and former dean of Harvard Medical School.

Nursing School Founded at Yale.—On April 24th, at New Haven, Conn., President Angell announced the establishment at Yale of the first university undergraduate school of nursing in the United States, the funds for which are to be provided by the Rockefeller Foundation.

Woman's Medical Society Convention.—The Women's Medical Society of New York State will hold its seventeenth annual convention at the McAlpin Hotel, Thirty-fourth Street and Broadway, Monday, May 21, 1923. This meeting is to be called at 9:30 a. m. and the banquet set for 7 p. m. The scientific program has been announced and may be obtained from Dr. Rosalie S. Morton, 26 East Sixty-third Street, New York City.

Hospital Has Celebration.—The New York Nursery and Child's Hospital at Sixty-first Street and Amsterdam Avenue, celebrated its one hundredth anniversary. It is the oldest children's and foundlings' hospital in America and the first maternity hospital to complete a century of service. In that time 75,000 babies have been born there. The hospital was founded on April 29, 1823.

Pharmacopœial Trustees Entertained in Cincinnati.—The Board of Trustees of the United States Pharmacopœia met in Cincinnati on May 4th and 5th for the transaction of business connected with the publication of the tenth edition of the United States Pharmacopœia, the manuscript of which is rapidly nearing completion. The members of the board in attendance at the meeting included: Dr. Solomon Solis Cohen, Philadelphia; Dr. Henry M. Whelpley, St. Louis; Dr. James H. Beal, Urbana, Ill.; Dean F. J. Wulling, Minneapolis; Prof. E. Fullerton Cook, Philadelphia, and Samuel L. Hilton, Washington.

London Fellowship of Medicine.—At a meeting of the Fellowship of Medicine held on Friday, April 13th, at the Royal Society of Medicine, a plan, brought forward by the nonundergraduate hospitals in London was accepted to take immediate steps to meet the needs of two classes of postgraduate students, those requiring short general refresher courses and those requiring advanced courses in the special departments of medicine and surgery. The short refresher courses will centre in a general nonundergraduate hospital, and each group will be responsible for three or four such courses during the year. The programs will be begun by a course at the Prince of Wales' General Hospital, Tottenham, assisted by the special hospitals belonging to the North Eastern Group, from June 11th to June 23rd. For graduates requiring more advanced instruction each of the special hospitals will undertake two or three courses during the year and in these it is hoped that specialists from the undergraduate hospitals will be willing to come to the special hospitals at the invitation of the staff to assist in lectures and demonstrations.

VIENNA LETTER

(*From our own correspondent.*)

VIENNA, *March* 30, 1923.

(*Continued from page* 505)

ANTISEMITISM IN VIENNA.

I mention all this because the American public is not conversant with it, and therefore cannot possibly grasp the present issue. In Austria, Germany, Hungary and Poland, antisemitism is not a movement like our own Ku Klux Klan, but much more widespread, and I believe that one of the accused would-be murderers in the Harden trial in Germany well nigh spoke the truth when he stated that fifty per cent. of the German people stood at his back, and that he would persevere on the path once taken.

While I was chairman of the reorganized American Medical Association of Vienna for ten months, I had plenty of opportunity to get into intimate contact with the present teaching staff of the medical faculty. The courses most favored by our American confrères over here are those held in the eye, ear, nose and throat departments. About seventy-five per cent. of the American physicians here attend those clinics. The ear clinic is in charge of Neumann, the throat and nose clinic of Hajek, and the skin courses held by Professor Ehrmann are quite in favor. All three are Jews, and so was the late Wertheim, a brilliant professor whose gynecology and obstetrics courses were popular with American physicians. The chair is now occupied by Kermauner and Peham, whom nobody knew outside the Court of the Hapsburgs. Professor Halben, a Jew, did not get the chair in spite of his epoch making studies on ovarian hormones. Whenever there is now a vacancy at the university, the chair is given to men for their political convictions, not for their scientific achievements. A case in point is the chair for pathological anatomy, vacant since the death of Weichselbaum. The Senate of the university offered this position to Aschoff, of Germany, who suggested, while refusing to accept the chair, the Viennese pathologist Sternberg (a Jew) as the proper candidate. Another case in point is Professor Leopold Freund, who brought before the Medical Association of Vienna the first case of hypertrichosis treated successfully by röntgen rays twenty-five years ago. He was the first man who recommended the use of x rays in the treatment of infectious skin diseases (favus, sycosis, herpes tonsurans). His first communications were met with great incredulity and scepticism on the part of the rest of the faculty, and in spite of the fact that Professor Freund was the pioneer in our knowledge of the biological and therapeutical effects of röntgen rays, his genius was never given a fair chance at the clinics of Vienna—simply because he was a Jew.

The present incumbent of the chair of röntgenology, Professor Holzknecht, recognized Freund's great merits, and even admitted—in the course of a session of the Medical Association of Vienna, held October 27, 1922—that he, Holzknecht, had had to abandon his own method and go back to the method of treatment advocated twenty-five years ago by Freund. Yet Freund, who is a Jew, is sidetracked, and will remain so for the rest of his life. Court Counsellor Professor Eder also pointed out the great merits of Freund in an editorial in the *Neue Freie Presse* of January 6, 1922; but Freund was not given any department, any opportunity to unfold his genius —he is a Jew.

This tendency to purify the faculty of Jewish talent is rampant just now, and—in my opinion—it constitutes one of the many reasons for the downfall of the medical faculty of Vienna. The present rector of the university, Karl Diener, found the courage to advocate publicly the exclusion of Jewish students and Jewish professors from the university, and seconded the demands of the German-National students as regards the restriction of the attendance of Jews to ten per cent., thus following the example set by highly civilized Poland and Hungary with their numerous clauses. At the same time he extolled Eduard Suess, his teacher and former rector of the Vienna University, in a eulogy describing him as one of the greatest of pathfinders, not omitting to mention his teacher's Protestant faith. He was evidently unaware of the fact that the mother of Suess, Zdekauer by name, was of Jewish extraction.

When the committee of bankers and industrial magnates, whose contributions help to keep the university from closing its doors, threatened to stop their contributions to an institution of sham freedom of thought, the Academic Senate of the University resolved, at its session of December 19, 1922, to contradict the political enunciamento of its rector by stating that the demands of the German students could not form the basis of negotiations, because they were not in conformity with the State laws.

While the university thus, so to speak, saved its face, it remains an undubitable fact that political parties dominate the university, that political influences mete out the vacant chairs to the followers of the various political bosses. It is the same atrocious element which murders men like Rathenau, Harden and others. A defeated race seeks its scapegoats.

VIENNA COMMERCIALIZED.

Vienna, the easygoing city of the continent, the city of artists, musicians and poets, is undergoing a painful metamorphosis—it is assuming all the earmarks of a commercial city. This statement is borne out by the disappearance of a great number of the coffee houses for which Vienna was once famous all over the world. These coffee houses served a manifold purpose; one could not only—in former times—get a cup of delicious coffee and cake there, but they were the meeting places of many business people, who transacted their business at the various tables, thus saving themselves the expense of maintaining costly offices; and they were the *rendezvous* for society, where many a young man met his fate. Some of the best known coffee houses also leased part of their space for private social gatherings, dances, clubrooms and so forth. In place of these coffee houses we now find new banks. A large number of these have shot up all of a sudden, like mushrooms after rain. The bankers were apparently the only people who could pay the exorbitant lease demanded by the coffee house proprietors. Considering the endemic gambling disease which has taken hold of the entire population—fortunes have been made and lost every day on the stock exchange by gambling in *valuta*—the socalled bankers were apparently the only people who made money.

In the place of a good many of the coffee houses we also find large offices for the purpose of handling the transit business between the newly born, independent states (Poland, Czecho-Slovakia, Jugoslavia) and the North, West and South of Europe. Vienna, due to its geographical location, seems to be predestined to functionate as a warehouse between the East and the West, the North and the South of Europe.

The people at large have lost all their idealism; they are quite mercenary. While the Viennese always looked upon foreigners as easy marks (*Würzen*), they have added to their peculiar easy going charm a new trait—that of raw arrogance. Wherever and with whomsoever one speaks, whether the person belongs to the laboring socialistic classes, to the intellectual middle classes or to the dethroned, formerly leisurely living aristocratic classes, after a short time one is bound to hear the remark, "Just think! this used to cost two kronen, now it costs three thousand kronen." All their thoughts are taken up in drawing comparisons between the former price of things and their present price.

No class of people has been struck so hard by the depreciation of the money as the older generation, who thought they could live, in their declining years, on the interest on their hardearned savings. The real estate owners and house owners have been getting no income at all because the law, introduced by the socialistic party, prohibited the increase of rents, thus bringing the landlords face to face with beggary. The net yearly income of a fourstory house —if there was any net income at all—equaled the price of a loaf of bread!

The quarter million of state employees and the laboring men suffered less, on account of the enactment of the index law, which was administered by a committee kept permanently busy figuring out the cost of living for every month; the more the money depreciated, the higher was the cost of living. The index law simply stated, for instance, that the cost of living for the past month was seventy per cent. higher than in the previous month, and the salaries and wages of all employees, State and industrial, therefore had to be automatically raised by seventy per cent. No matter how much the money depreciated, it is thus evident that the working classes always received wages correspondingly higher. More "money" had to be printed, and with the increase of printed paper money, its value again fell. It was a vicious circle, which nobody could stop. And the masses of the people did not care because, after all, they always got equivalent money, although they could not do more than buy mere necessities with those big wages.

As most of the food products, coal, wool and leather had to be imported and paid for in foreign coin, the people soon paid no attention to the thousands of kronen they got, but merely asked themselves, "What amount of food, clothes, shoes, coal, and other commodities can I buy with that sum?"

The newly arrived foreigner, who thought himself a very liberal, freely tipping person, soon found out that the thousands and ten thousands of kronen he was meting out for tips were not appreciated. Everybody wanted foreign coin. I understood, for instance, why the nurses at the clinic at which I was working did not even thank me for the pound of ham I presented to them. "Of course," they said, "it's only a dollar you gave us, and what is a dollar to you?" And when I asked one of them to please help me into my fur coat, she stepped aside with "Oh, not *I*!" Then the other came up and said, "Oh, but *I* shall help the Doctor! It means a bottle of wine for Christmas." Think of such a frame of mind in people who were supposed to assist the sick.

Everybody, from the street urchin to the professor, has been gambling on the Stock Exchange, speculating on the fall of the kronen. One day, when two dogs were needed at the clinic for some experimental work, the *Diener* (servant) asked me four thousand kronen apiece. I wondered at the big price, whereupon he immediately retorted, "Oh, what's that to you? Not even half a dollar!" He did not know that I had changed my dollars a month ago, when I got only seven hundred kronen for the dollar—not eight thousand, the price the dollar commanded a month later. He evidently did not realize that four thousand kronen meant six dollars to me, not half a dollar.

Is it to be wondered at if, under such conditions, every foreigner should be considered as a cow to be milked? That every American was asked by the professors to pay forty to one hundred times more kronen for the teaching hour, in the courses given, than any other foreigner? I pointed out that discrimination against Americans, which was going on at the clinics in the American Medical Association's circular of March, 1922, and when our committee argued with the committee of professors for hours on the injustice of such procedure, the professors insisted that their mental goods did not depreciate as compared with what they were before the war, and that was sufficient reason for Americans to have to pay the prewar prices. But Americans refused to pay more than French or Swiss or English physicians had to pay. So the professors tried to break up the American Medical Association organization—they did not like the idea of being checked up too closely. There were always enough Americans who would pay any price to get the time of this or that teacher and the teacher thus overpaid by one or two Americans had no time left to give courses to the "cheap skates" of the organization, and the organization really would have been destroyed if we had not published broadcast the statement of March, 1922, about the medical profiteers of Vienna. This move—and this move only—made it imperative for the teaching staff to have the statement publicly retracted by the American Medical Association. The American Medical Association did so, after all their demands for fairness had been granted, and the fighting officers made way for a new set of peace officers.

This fight of ten months' duration revealed to me such an appalling decadence of ethics and morality, such a lack of the sense of justice and fairness among a class of people supposed to rank as leaders of the cause of truth and fighters of lies, it has revealed to me such a base level of mind and soul in the teaching staff of what was once one of the most renowned universities, that I was at a loss to understand it until I began to look upon them as a mere part of the people at large—a people at large utterly decadent.

(*To be continued.*)

Book Reviews

THE TRIALS OF THE YOUNG PHYSICIAN

Doctor and Patience. By HAROLD M. HAYS. With Introduction by Dr. Alexander Lambert. Boston and New York: The Cornhill Publishing Company, 1923.

Dr. Hays has earned an enviable reputation as a surgeon and a writer on medical topics pertaining to his specialty. We fear, however, this attempt to portray, in the form of a novel, the trials and tribulations of a young physician beginning practice in a large city like New York will not add materially to his standing as a writer of fiction. Though nobly conceived, the author has not succeeded in drawing his characters convincingly. The hero, it seems to us, is too virtuous, and his faults, if he has any, are so few that he must have died very young. He was altogether too good and too innocent to live long in this dreadful world; and we believe his awful horror at the friendly suggestion that he "split" fees for referred cases would hardly meet with much sympathy from many of the surgeons who are filling our hospital beds with operative cases, not only in New York but throughout the country.

The villain, also a doctor, comes to an untimely end by violence, according to the rule that the wages of sin is death. But he wasn't such a bad fellow at heart, in spite of his illegal doings. Our hero seems to look at him through a one track eye, if such an expression may be permitted, seeing only the obvious black in him but entirely overlooking the hidden white which even the greatest sinner among us has in some measurable degree. One character that stands out like a giant among pigmies is Evelyn, the doctor hero's practical wife. Her picture is well drawn and she typifies the difficult and sacrificing life which most doctors' wives live. Without her aid and comfort we wonder what sort of a hero our hero would have been.

The volume makes an interesting hour's reading, and can be read with profit and pleasure by doctor as well as layman.

THE NEW PHYSIOLOGY

The New Physiology in Surgical and General Practice. By A. RENDLE SHORT, M.D., B.S., B.Sc. (Lond.), F.R.C.S. (Eng.). Fifth Edition, Revised and Enlarged. New York: William Wood & Co., 1922.

Because of the rapid changes in our views of the relation between physiology, on the one hand, and medical and surgical problems, on the other, the author has practically rewritten each of the editions of this useful and popular work, which have so rapidly succeeded one another. The present volume, therefore, may be accepted as being practically a new book. Three entirely new chapters appear in this edition, treating of the dietetic factor in the etiology of appendicitis, the functions of the kidney, and the physiology of muscular exercise. Herapath has rewritten the chapter on the heart. The physiology of the genital glands in both sexes is fully considered in the light of the most recent studies.

Commenting on the twenty-four chromosomes with which the human fetus starts life, and in which, quoting Weismann, its entire heredity is bound up, including the impulse to assume the general shape of mankind; more or less resemblance to the facial appearance and even the tone of voice and character of its parents—the author wonders how all this is crowded into such microscopic objects and considers this the greatest marvel in biology.

The work is attractive, both instructing and entertaining. There is a vast fund of information, valuable not alone to the physiologist, but to the active physician and surgeon whose daily work must necessarily depend on a practical and up to date knowledge of the physiological functions of the various organs of the body.

PRACTICAL PHYSICS

Practical Physics. By J. A. CROWTHER, Sc.D., F.Inst.P., Sometime Fellow of St. John's College, Cambridge. London: Henry Frowde and Hodder & Stoughton, 1922.

The volume under review is intended by the author to cover the practical work in physics which usually is demanded of a student entering a medical school. It is distinctly elementary in character; nevertheless it covers a vast amount of ground and presents the subject in an interesting and instructive manner which must make its appeal to the student.

The author has divided his subject into five books—practical measurements, mechanics and hydrostatics, heat, light and sound, magnetism and electricity. One hundred and forty-four experiments are fully described, each preceded by a statement of what is intended to be proved. The illustrations are clear, simple and plentiful, and the typography is all that could be desired. The work will be distinctly valuable to the student and a welcome addition to the many that have preceded it on the same subject.

COLLECTED PAPERS

Mitteilungen aus der Medizinischen Fakultät der Kaiserlichen Universität zu Tokyo. xxviii Band 2. Heft. Tokyo: Verlag der Kaiserlichen Universität, 1922.

N. Sekita reports the results of his experimental studies on phosphorus poisoning, including the effect of glucose and alcohol upon the fat changes, the respiratory metabolism, the fate of the introduced glucose and the disturbances in the synthesis of urea in animals poisoned by phosphorus.

E. Komiya contributes some facts on hyperchromatic anemia. Four cases are reported, together with their histories, and the blood, necropsy and histological findings. The diagnosis is discussed and the various theories on the subject are criticized, giving special attention to the significance of megaloblasts and the changes in the color index, the size and the volume index of the erythrocytes.

T. Ishikawa reports on the pseudoleucemic changes in the external skin and eyelids. The histology, together with the necropsy, hematology and histology of a case are given. The histological changes in the skin are carefully investigated, including the absence of lymphocytic infiltration in the subpapillary zone and the mitotic figures in the lymphatic foci. The cause of the aleucemia, the hemorrhages into the lymphatic foci of infiltration, the origin of the pseudoleucemic skin changes and the pathogenesis are discussed. The histology, pathogenesis and origin of the pseudoleucemic tumor of the eyelids and the pseudoleucemic changes in the eyeball are also taken up.

S. Nakagawa contributes his studies on ferments as to the lability of the sojaurease and on the socalled auxoureases and coenzymes. The lability of the sojaurease in dilution and the relation between temperature and ferment destruction during the activity of the ferment are discussed. The action of auxoureases were tested with serum, casein solution, solution of Witte peptone, glycocoll, ajinomoto and sodium nucleinate. The experiments on the coenzyme of sojaurease were conducted with boiled ferment solution, ferment solutions previously treated with alkalis and with dialyzed ferment solution. Experiments were also conducted with the ash consituents and with the germinal urease of glycine hispida. The effect of the total volume of the digestive mixtures upon the ferment activity was also investigated.

SPIRITISM

Subjective Concepts of Humans Source of Spiritistic Manifestations. By John J. Donnelly. New York: The International Press, 1922.

The author of this book has substituted for formerly accepted adherence to orthodox religion a strange animistic theory of mental activity as it operates in the relations of human beings. His interest is chiefly in carrying this over to a spiritistic world, which he explains by his concept. His statement is "that the intelligence of each sentient being begets a subjective concept of each sentient being met, and with whom it exchanges mutual recognition." The development of his idea of the spiritual world and his descriptions of mental life take him along a foggy path of thinking which touches on one hand upon some facts of pragmatic truth but on the other brushes too closely upon fantastic conceptions, his own dogmatic assurances of which fail to convince the reader.

ENLARGEMENT OF THE PROSTATE

Enlargement of the Prostate: Its History, Anatomy, Etiology, Pathology, Clinical Causes, Symptoms, Diagnosis, Prognosis, Treatment; Technique of Operations and Aftertreatment. By John B. Deaver, M.D., LL.D., Sc.D., F.A.C.S. Assisted by Leon Herman, B.S., M.D. Second Edition, with 142 illustrations. Philadelphia: P. Blakiston's Son & Co., 1922.

Deaver emphasizes the fact that the surgery of prostatic obstruction has been perfected to a remarkable degree since the publication of the first edition of this work some fifteen years ago. In the earlier work he advised prostatectomy "only after all palliative means had been tried without success"; in the present work the operation is recommended as a primary procedure, being considered far safer in the average case than any form of palliation. While the author makes no pretense at presenting anything that is new in this volume, he has aimed to make the work distinctly practical in character and therefore has eliminated many of the theoretical considerations and refinements in technic proposed by various authors, which merely serve to confuse the reader by their multiplicity and contradictory claims. The same method has been applied to the consideration of the laboratory tests, only those that have been tried and found useful being considered at any length.

The work is written in Deaver's characteristic style and thoroughly covers the subject. The preoperative and postoperative methods of treatment are fully described and constitute a valuable contribution to this highly interesting and useful work.

EXPERIMENTAL BACTERIOLOGY AND INFECTIOUS DISEASES

Die Experimentelle Bakteriologie und die Infektionskrankheiten mit besonderer Berücksichtigung der Immunitätslehre. Ein Lehrbuch für Studierende, Arzte und Medizinalbeamte. Von Dr. W. Kolle, Institutes für experimentelle Therapie in Frankfurt a Main. Sechste, umgearbeitete Auflage. Ester Band. Mit 41 grösstenteils mehrfarbigen Tafeln, 79 abbildungen im Text und 7 Kartenskizzen. Zweiter Band. Mit 73 grösstenteils mehrfarbigen Tafeln, 135 Abbildungen im Text und 5 Kartenskizzen. Berlin und Wien: Urban & Schwarzenberg, 1922. Pp. xvii, xi, 1376.

A sixth edition and the translations into several languages are evidence of the popularity and excellence of these two volumes. Both the authors and the publishers are to be congratulated upon this publication. It deals exhaustively with this very extensive subject, not only as it was elaborated in Germany but also, to a great extent, as worked up by foreign laboratories. Emphasis is laid upon the important results of recent investigations and the difficulties encountered are pointed out to pave the way for future research, especially in the fields of epidemiology and the prophylaxis of epidemics.

Much new material has been added and there are many rearrangements of the material in this edition. An extensive and up to date (1921) bibliography is appended at the end of each chapter. The work is of great value to the pathologist, health official, epidemiologist, hygienist, physician and student and it should be part of the equipment of every pathological laboratory. The marginal headings enhance its value as a reference book. The illustrations are excellent and the delicate shades of coloring are such as are rarely seen. Both the practical and theoretical aspects of infectious diseases and laboratory work from the bacteriological viewpoint are taken up. The principles of immunity are given special consideration.

The first volume deals with the microscope and microscopy in all its branches; the general morphology and biology of pathogenic microorganisms; the disinfectants and the fundamental principles of disinfection; infection, infectious excitants, their specificity and the mixed and secondary infections; immunity, protective inoculations and the production of protective and curative sera in practice; antitoxins, bacteriolysins, agglutinins and precipitins; serodiagnostic methods of examination; anaphylaxis and general remarks on bacteriotherapy and serotherapy; and the various specific bacterial diseases. A considerable part of the second volume is devoted to the various spirochetal diseases and the chemotherapeutic problems, with special consideration of the chemotherapy of syphilis. Among the rare and tropical diseases, trypanosomiasis (animal and human), the coccidia, the piroplasmodia, the filterable disease excitants, papatacci and dengue fever, lyssa, foot and mouth disease, verruga peruviana, rinderpest, five day fever, filariasis and bilharziasis are considered with much more detail than is usually given these subjects. The infectious diseases of unknown origin are treated.

The thread fungi and yeasts are also discussed. In short, there is little, if anything, that was omitted from this monumental and beautiful work on experimental. bacteriology and infectious diseases.

OPOTHERAPY

L'Opothérapie du Practicien. By L. LEMATTE. Paris: A. Maloine & Fils, 1923. Pp. 239.

This is a practical little book suited to guide the general practitioner to an intelligent use of glandular substances in medicine. In simple manner the writer presents the various forms in which these may be used with the methods of preparation which give them greatest efficacy. Methods of administration are also given. A large part of the book is devoted to the maladies in which opotherapy is of service.

COUEISM

Coué for Children. By GERTRUDE MAYO. With a Preface by Emile Coué. Illustrated. New York: Dodd, Mead and Company, 1923. Pp. viii, 126.

There are many individuals of keen discernment who realize more and more the lamentable fact that the mass of people will not think for themselves. Or in the words of Freud, men and women everywhere shrink from facing reality. When and how would this evil ever be corrected if Couéism were able to spread itself over adults and children alike? Immediate advantage is no doubt brought about, even as this fulsomely enthusiastic author truly reports. Yet it is easy to detect the ground of the effect in a psychic attitude of transference, in a confidence based upon dreamy ideals the wholesome lasting effect of which one may well question. The further effect of encouraging in the younger members of society that attitude of trustful submission rather than cleareyed question, mumbling of magic formulas rather than resolute gripping at stern facts themselves, is a menace which may well be faced. "Caressing them tenderly and talking to them softly," words quoted by the author of this book from Coué himself, gave a note of the danger to the psychic stamina which is only too well known by the psychoanalyst. No human method but must touch upon some truths. So it is with Couéism as here presented. But the few glimmers of truth are in a dangerously false setting.

COLLECTED PAPERS

Selected Papers and Addresses. By WILLIAM WILLIAMS KEEN, M.D., Philadelphia: George W. Jacobs & Co., 1923. Pp. 340.

The papers collected into this small volume appeared originally in various periodicals throughout a number of years. They are on many subjects and for many types of reader, including the physician, the educator, the missionary, the historian, the soldier, and the layman. Dr. Keen in his preface requests the reader to keep in mind the fact that they were addressed to wholly different audiences at wholly different times; and also to bear in mind their dates, since progress in knowledge and in technic have altered many viewpoints. Essays of special interest to physicians are: The graduation ceremony, with an account of some modern surgical celebrations, a short history of such occasions, ancient, medieval and modern; the community of interest of the medical school and the public; before and after Lister; dangers of ether as an anesthetic; story of the three tablets (to Dr. James Markham Ambler, of the Arctic exploring steamer *Jeannette;* Dr. Jesse W. Lazear, who offered himself as a subject for yellow experimentation; and Dr. William M. Wightman, who died from the same cause); a world of billions (a study of the blood); the red cross and the antivivisectionists; some of the things we surgeons as a profession stand for; and vivisection.

MEDICINE

Lehrbuch der Grenzebiete der Medizin und zahnheilkunde, für studierende, zahnärzte und Arzte. Bearbeite und Herausgegeben von Dr. JULIUS MISCH. Zahnärzt in Berlin. Zweite Band. Second Edition. Leipzig: F. W. C. Vogel, 1922.

This volume is the joint work of a staff of colaborators as follows: dermatology by Ledermann; gynecology by Büttner; rhinolaryngology by Finder; otology by Gutmann; occupational diseases by Koelsch. The editor has collaborated in each of these sections as a stomatologist. The number of pages is 672 with 351 illustrations which include a number of fine colored plates. The two detached volumes which make up the work of Dr. Misch appeared originally in 1914 in a single binding. In the absence of the first volume it is impossible to give the present one an adequate review.

SURGICAL ANATOMY

A Manual of Surgical Anatomy. By LEWIS BEESLEY, F.R.C.S. and T. B. JOHNSTON, M.B., Ch.B. Second Edition. New York: William Wood & Co., 1923.

This is an exceptionally good work on surgical anatomy. The illustrations are clear and well interspersed with x ray plates and diagrams in color, showing various anatomical structure. The index is well arranged so that one is able to find almost any anatomical structure. The authors have a thorough knowledge of surgery as their surgical descriptions of procedures are excellent. The reviewer can thoroughly recommend this work.

ANATOMY

A Manual of Practical Anatomy. Part III. By THOMAS WALMSLEY, New York: Longmans, Green and Company, 1922.

This third volume completes the set of dissectors written by Walmsley. The former volumes were reviewed in this JOURNAL. This last one is in keeping with these and the entire set may be commended to the student of anatomical dissection.

FIRE AND ICE

The Long Journey. By JOHANNES V. JENSEN. Translated by A. G. Chater. New York: Alfred A. Knopf, 1923.

In vivid, poetic form Jensen has given birth to this first volume of the trilogy of mankind. It makes wonderfully interesting reading, even to the person unacquainted with the details of geological and anthropological growth. Coming as it did for the reviewer on top of Carveth Read's *Origin of Man* it was as a breathtaking illuminated text of all one's readings on the subject. In short, it gives the picturesque final form to our ideas about the whence and wherefore of most things. We await anxiously the other volumes to see whether the thousand years of man's increasingly rapid whirling through intelligence has been as fascinatingly and skillfully depicted as his billions of years of groping to human thought.

HUMOR IN THE DRAMA

Mary, Mary, Quite Contrary. By St. John G. Ervine. New York: The Macmillan Company, 1923.

A very light playlet on a theme of elemental simplicity. The temperamental actress alternately lives up to her vagaries and astounds the public by demonstrations of shrewdness and a woman's heart. Lay figures, all of them, strutting as we like to have them, and for that reason disappointing to those of us who have appreciated the fine reality of Ervine's earlier plays. One can pick the preordained laughs from the page. An ideal play for the graduating class of a high school! No problems, no sexy dangers!

ANGER

Anger: Its Religious and Moral Significance. By G. M. Stratton. New York: The Macmillan Company, 1923.

A very good essay showing the psychopathology of sadism in religion. The study was not intended to serve this purpose as it is written in a rather serious vein seeking a justification for sadistic trends in religion, but it may nevertheless be utilized, especially in connection with some of the hate mechanisms in epilepsy, dementia precox and religious mania.

MEDICOLITERARY NOTES

Dr. Taliaferro Clark and Dr. Edith B. Lowry, of the U. S. Public Health Service, are joint authors of an article in *Public Health Reports* for February 16th on Health Scoring for School Children, a Practicable Plan of Followup Work by the Child. In every department of education except health it has been found necessary to set a standard toward which the child can work. Following this line of thought, an attempt has been made to establish a health standard that can be lived up to by everyone, adult or child. The article describes such a standard that has been tried out in a few of the states with success.

* * *

In an article in the May issue of the *Atlantic Monthly,* entitled Experiences in Dying, Dr. J. D. MacKenzie tells of five personal experiences in four different countries which brought him to the verge of death. His conclusion is that death must be an "easy, gentle thing, a pleasant, sweet release."

* * *

A recent number of *Public Health Reports* gives an interesting outline of the remarkable progress of public health activities in Jugoslavia since the close of the war. Among these activities have been the passage of new health laws, the provision of sections for health education for the sanitary districts of the country, which have held more than four thousand meetings and distributed literature and used films, the establishment of sixteen bacteriological stations for the study of infectious diseases, and of a special institute for the study of tropical diseases, a school for nurses has been greatly enlarged, a special study is being made of malaria, several Pasteur Institutes have been enlarged and their equipment increased to include other branches of medicine, a hospital for the study and treatment of trachoma has been opened, thirty tuberculosis dispensaries have been established, and pavilions for the treatment of venereal diseases have been greatly enlarged.

* * *

The report of the New York State Veterinary College at Cornell University, covering the year 1921-1922, has recently been issued for distribution.

* * *

The Antiquity of Disease, by Dr. R. L. Moodie, of the University of Illinois, is the latest volume of the University of Chicago Science Series, published by the University Press. The book is popular in treatment and is distinctly for the layman, but its subject matter and sound scientific basis make it of value also to the physician.

* * *

Two volumes of medical interest have just been published by Brentano's and the Century Company, respectively. They are *Right Food the Right Remedy,* by the well known dietitian,Charles C. Froude, and *Teeth, Diet, and Health,* by Dr. Kurt H. Thoma, assistant professor of oral histology and pathology in the Harvard Dental School. Both books are designed particularly for the general reader.

* * *

The Woman's Medical Journal for February contains an outline of the proceedings of the Second International Congress for the Protection of Mothers and Infants, held in Paris last summer.

* * *

The pupils of Freud in Vienna have founded recently two organizations, the Society for Applied Psychopathology and Psychology, and the Psychoanalytical Reunion. Vienna has had for some time a psychoanalytical dispensary where the poor are given analytical treatment, and where young physicians have the opportunity to learn psychoanalytical methods.

* * *

The *World's Work* for May contains an article by Samuel Hopkins Adams on the new profession of health officer. The title is Doubling the Guards on Health.

* * *

As a result of a gift from the Commonwealth Fund to the National Committee for Mental Hygiene, the Division on Prevention of Delinquency has a fund for fellowships in psychiatry. Those securing fellowships will be placed under training in the clinics now being conducted by the division. The object of the fund is to prepare properly qualified psychiatrists for positions in connection with permanent clinics that are now being organized through the activities of the demonstration clinics conducted by the National Committee for Mental Hygiene. The fellowships will be awarded by a committee composed of Dr. Thomas W. Salmon, Mr. Barry C. Smith, and Dr. Frankwood E. Williams. Those interested in securing information regarding the fellowships may address Dr. V. V. Anderson, Director of the Division on Prevention of Delinquency, the National Committee for Mental Hygiene.—*Mental Hygiene Bulletin.*

Practical Therapeutics

SPINAL ANESTHESIA IN RELATION TO ASSOCIATED THERAPEUTIC PROBLEMS*

By W. Wayne Babcock, M. D.,

Philadelphia.

In the physiological action of spinal anesthesia, the effect on the sympathetic system stands out as of great practical importance. With the interruption of conduction in the anterior and posterior nerve roots, and of the rami communicantes of the spinal segments that are acted upon by the drug, the predominant feature apart from the analgesia and the palsy is the great fall in blood pressure. A fall registered by twenty to thirty milligrams of mercury is moderate; thirty to fifty not unusual; and a fall in the systolic pressure in the radials to zero is occasionally seen. Several factors contribute to this vascular hypotension. The vascular relaxation from the paralysis of the vasomotor nerves is associated with a relaxation of the voluntary muscles, reducing the normal support to their contained veins. The abdominal walls also relax, and with the associated abolition of abdominal respiratory movements, the supporting pressure on the intraabdominal vessels is reduced. With most conditions producing a fall in blood pressure, there is an increase in the pulse rate, but in spinal anesthesia, anomalously, the heart beats slower as the pressure falls. A reduction in the heart rate from eighty or ninety to sixty, fifty or forty-five is uncommon. Being largely released from the stimulating sympathetic influence, the heart has the inhibitory action of the vagi practically unopposed. With the slower circulation, the cavities of the heart fill more slowly and, with the reduced stimulus from the lessened *vis à fronte,* the contractions of the heart become weaker so that the circulation is slowed not only by the widened blood paths but also by the slower, weaker cardiac contractions. There is produced by spinal anesthesia, therefore, a vascular system largely cut off from normal vasomotor impulse, a condition favorable for the determination of the stimulating power of drugs upon the peripheral vessels, locally upon the heart, and possibly also an added means for estimating the depressing action of drugs upon the pneumonogastrics. Spinal anesthesia is the curare of the vasomotor system.

In other words, one may effectively cut off by the intradural injection, all influences emanating from many segments of the spinal cord, for a limited period of time, and during this time may test the action of a variety of drugs upon the peripheral vessels and heart. Bound up in these experiments is the solution of the predominant danger of spinal anesthesia, for it is the fall in pressure and the second respiratory failure from ischemia of the centres in the medulla that have much to do with collapse from this anesthetic. The dangerous effects upon the upper cervical nerve roots can be largely avoided by the technic of the injection, but the fall in blood pressure is often the chief concern of the surgeon.

For eighteen years we have used spinal anesthesia in over sixty per cent. of our operative work, and have obtained impressions as to certain actions of a number of drugs used during the period of anesthesia. Some of these impressions have been confirmed by blood pressure and other studies; many are fragmentary and require confirmation. They are presented as elementary observations, with the hope of stimulating further investigations in this field.

DIGITALIS.

As would be expected, digitalis acts so slowly as to render it necessary to administer the drug hours or days before the induction of spinal anesthesia. Therefore, it is much more difficult to study its action than that of a rapidly acting vascular stimulant, and impressions must largely replace accurate records. It apparently has little action on the normal heart under spinal anesthesia, and while it does not prevent a marked fall in blood pressure, it seems to enable the weakened heart better to withstand such a fall. It seems, therefore, a valuable drug in the preanesthetic preparation of many cardiopaths.

ETHER.

Very light etherization, as by inhalation, seems to act as a definite stimulant, producing a slight increase in the blood pressure (two to twelve milligrams of mercury) and an improvement in the patient's condition during the stage of hypotension of spinal anesthesia. The second or third stage of etherization is probably unsafe, tending to increase the dangers of the anesthesia, and of course these stages are practically unnecessary during the period of relaxation of spinal anesthesia.

NITROUS OXIDE.

As with ether, a very light gas oxygen analgesia improves the condition of patients in spinal anesthesia, increasing the blood pressure five to twenty points. It is dangerous when pushed to a full or prolonged narcosis. In no case should sufficient nitrous oxide be given to cause cyanosis. In spinal anesthesia, cyanosis and the accumulation of carbon dioxide in the blood largely fail to improve circulatory hypotension.

AMMONIA.

Ammonia used in the form of the aromatic spirit, and administered by inhalation, has a slight stimulating effect. A rise in blood pressure of from six to twelve milligrams of mercury has repeatedly been observed from the inhalation.

STRYCHNINE AND CAFFEINE.

These drugs seem to have little effect in increasing blood pressure during spinal anesthesia.

PITUITRIN.

An extensive use of pituitrin, given subcutaneously or intramuscularly, has given us the impression that the drug has some value in maintaining blood pressure in spinal anesthesia. We have not been able to prove this definitely, however, and one c. c. of the surgical solution of pituitrin may be injected intravenously during the period of hypotension of spinal anesthesia with no influence upon the blood pressure. As a circulatory stimulant, in contrast with epinephrine, it seems to be a very weak and uncertain drug, and may be valueless in spinal anesthesia.

---

*Read at the annual meeting of the American Therapeutic Society, May 1 and 2, 1922.

EPINEPHRINE.

Given intramuscularly or subcutaneously, ten minims of epinephrine produces a slight effect upon the blood pressure, while two to fifteen minims administered intravenously may produce a violent stimulating action, sending the blood pressure up thirty, forty to eighty points in two or three minutes. The effect is so sudden, and in some patients so violent, that the drug should be administered very cautiously and in dilute solution. Some robust patients will show overstimulation from one to three minims, while on the other hand debilitated or greatly depressed patients may require sixty or eighty minims of a one in a thousand solution to produce a moderate degree of stimulation. Practically, therefore, we inject the solution slowly until the circulation shows the first sign of improvement, when the injection is stopped, to be resumed if the pressure is not sufficiently elevated or maintained. The effect may pass off and be followed by undesirable secondary depression in twenty or thirty minutes, therefore for some patients it is desirable to tie a needle in the vein and use an intermittent injection of dilute solution to produce a sufficiently prolonged effect. In most cases, however, the hypotension of spinal anesthesia has largely passed by before the secondary reaction from the epinephrine occurs. It is probably the most powerful drug for raising blood pressure during spinal anesthesia. The effect is observed in the wound by the increased bleeding and the appearance of spouting vessels. Respiration usually improves after stimulation of the circulation, together with the color and warmth of the skin. If, from the hypotension, the heart has stopped beating, then large quantities of a solution containing epinephrine must be introduced into the vascular system, and rhythmic compression of the heart carried out to force out the old blood and to permit the epinephrine to enter the coronary vessels. The free introduction of very weak (1 to 60,000 to 1 to 100,000) epinephrine solution, in combination with procaine, for local anesthesia improves the condition of the circulation under spinal anesthesia, and therefore renders the operation of greater safety. Five hundred to two thousand c. c. of such a weak solution may be used with safety if the injection is not made into the blood stream.

For uniform effects in spinal anesthesia, it is necessary to observe the following technic:

1. The needle point must be free in the cavity of the arachnoid, and the cerebrospinal fluid must escape freely from the needle, otherwise the solution may be diverted from the nerve roots that it is desired to influence.

2. The specific gravity of the solution must be so adjusted with the position of the patient on the operating table that the proper nerve roots may be anesthetized. Owing to the usual marked fall in blood pressure, we prefer to inject a solution lighter than the cerebrospinal fluid, and to lower instantly the upper part of the body and continue the elevation of the pelvis until the drug has been fixed by the tissues and can no longer diffuse.

3. The concentration of the analgesic solution is important. The proper percentage strength varies with the different drugs employed. Some are much weaker than others, but in general the stronger the solution the more intense, the more diffuse, and the more prolonged the action.

4. The amount of cerebrospinal fluid withdrawn and the amount of fluid injected influences greatly the height and extent of the anesthesia. By withdrawing much cerebrospinal fluid, mixing it with the drug and reinjecting, high effects reaching the cervical roots or the cranial nerves may be produced. Likewise, the same amount of drug diluted by ten c. c. of liquid and injected will show a wider diffusion and higher anesthesia than when injected dissolved in but one c. c. of solution.

5. The force with which the injection is given influences greatly the diffusion and height of action in spinal anesthesia. A very forcible injection may cause untoward effects and death from the influence upon the cervical nerves, and the ensuing fall in blood pressure and paralysis of the diaphragm. An operator, therefore, who is not familiar with the influence of specific gravity, the position of the patient, the influence of drug concentration, and of bulk and force in making the injection, will have variable results, and may meet with disaster, whereas careful attention to these various details insures a remarkable uniformity influence of the drug, with the least danger.

DIGITALIS IN THE TREATMENT OF TOBACCO AMBLYOPIA

Preliminary Contribution

By M. R. Dinkelspiel, M. D.,
Wilkes-Barre, Pa.,
Formerly Instructor in Ophthalmology, Medicochirurgical College, Philadelphia.

The rapid improvement in several cases of tobacco amblyopia, associated with the usual involvement of the papillomacular fibres of the optic nerve, and central scotomata for red and green, in which digitalis was exhibited, justifies further observations.

Notwithstanding the opportunity afforded by the ophthalmoscope for direct inspection of a portion of the circulation, our knowledge of the intraocular manifestations of cardiovascular disease is practically embraced by pulsation of the retinal vessels, retinal hemorrhages, thrombosis, embolism, and venous congestion in valvular heart disease, exophthalmos and mydriasis from irritation of the cervical sympathic in aortic aneurysm, or the reverse in its paralysis; and of course, characteristic changes in the fundus from arteriosclerosis. Probably for this reason, digitalis does not occupy the position in ophthalmic therapeutics that it should, although its properties for promoting local nutrition as a circulatory stimulant are well known, as evidenced in chronic valvular heart disease, followed by compensatory hypertrophy. Ophthalmic literature is quite barren on this subject, with the exception of an occasional mention of digitalis as a circulatory stimulant, a specific reference to its use in toxic amblyopia by de Schweinitz (1), as follows—"and the circulation of the optic nerve may be stimulated by, the exhibition of digitalis and nux vomica." Likewise Hare (2), and Hanke (3).

This scarcity of ocular manifestations, and the frequently enforced abstinence from tobacco in cardiac disease, has likewise limited the field for observation. On the other hand, the synchronous response of the retinal artery to the systole of the heart, and the ability to view arteries, veins, and capillaries during life, in situ, offer alluring opportunities for the intraocular observation of the action of cardiac drugs. Pioneers have already appeared in this fertile field, especially along the lines of ocular blood tension—R. H. Elliot (4), Gaudissart (5), etc. The occasional alternate increase and decrease in the red intensity of the central artery of the retina, and its branches on the disc, in cases presenting the prodromal symptoms of glaucoma, no doubt due to pressure from increased tension, show the importance of the cardiac systole as an intraocular manifestation. An additional indication for an increased determination of blood to the eye for its local nutritional value is indicated, by the fact, recently mentioned by Priestly Smith (6), that it is known that the blood stream fall in pressure as they pass through the eye, although not known how the fall is distributed.

Mydriatics sometimes increase venous pulsation in normal eyes, and the presence of a spontaneous pulse has been investigated in a very painstaking manner by Elliot, (4) abstracted as follows:

"In a very interesting discourse on the arterial and venous retinal pulses, with full consideration of the anatomical and physiological factors that enter into their causation, a graphic chart is presented to explain every step in the progress of such pulsations marked off in tenths of a second. Then follows a statistical study of the venous pulse in a hundred healthy individuals; these persons came under observation for refractive conditions but were free from any signs of disease and those who were even intractable or nervous were excluded. Considering them as individuals, a spontaneous pulse was present in both eyes in forty-six per cent.; absent in both in forty per cent.; present in one eye only, in fourteen per cent. Of the first group, the pulse was even in both eyes in twenty-eight per cent.; uneven in the two eyes, in eighteen per cent. Of the group in which pulsation was absent, it could be elicited by pressure in both eyes in twelve per cent.; in one eye only eighteen per cent.; no pulse even on pressure, in twenty per cent. Dealing with the two hundred eyes, regardless of the patients they belonged to: Spontaneous pulse was present in forty-nine per cent.; absent in fifty-one per cent. Of the first group, pressure increased the pulse in 35.5 per cent.; stopped or diminished it in seven per cent.; had no influence in two per cent.; escaped notice in 4.5 per cent."

In toxic amblyopia due to tobacco, digitalis is only of value before the establishment of organic changes, but in the stage so often characterized by slight haziness and hyperemia of that portion of disc corresponding to the distribution of the papillomacular bundle of fibres, its action is often rapid, and enhances the value of strychnine or nux vomica, to a remarkable degree. Nux vomica admits of better control and dosing in the individual case than strychnine, with the exception of those cases in which there is no time for more prolonged observation. Gradually increasing doses of a good tincture of nux vomica, up to thirty or forty minims three times a day, if tolerated, combined with eight to ten drops of a potent digitalis preparation such as digalen, have in the main, given better results at my hands, than even the hypodermic administration of strychnine. The benefit of digitalis in toxic amblyopia from local blood nutrition, may eventually establish either the theory of Birch-Hirschfeld of a selective toxic action on the ganglion cells and axis cylinders; or that of Schieck of beginning bloodvessel changes; and there is also a diuretic action of digitalis, which, in the absence of further knowledge in these cases, although as yet negligible, cannot be overlooked.

Furthermore, in support of the value of digitalis in promoting optic nerve nutrition, there is hardly a disease due to infection in which the optic nerve is not sometimes involved. To this may be added those cases due to disturbances of metabolism, and those occurring during lactation, menstruation, pregnancy, and the puerperium.

It is generally conceded that in so important a drug as digitalis, varying in strength and physiological potency, a standardized preparation should be used. There are several of them to be had, my preference having been for digalen, reasons for which were pointed out in an article by me (7), and substantiated by fifteen years more of clinical experience. The dose, in cases of tobacco amblyopia, most successful at my hands, has been five to ten minims twice or three times daily, in addition to increasing doses of a physiologically standardized tincture of nux vomica, in increasing doses to the point of tolerance. Digitalis obviously should not be employed where systemic contraindications are present; and where atrophic changes are established, it is of doubtful value, and while it has no specific or selective value in these cases *per se*, it is a very valuable adjunct. I have had no experience with the use of phosphorus in the form of injections, recently advocated by Terson (8).

Early Signs of Rickets.—J. H. Thurshfield (*Lancet*, September 9, 1922) states that the presence of bone deformities in a rachitic child is an indication of delinquency on the part of the attending physician; such changes ought never to be allowed to appear. He lays great emphasis upon what he calls the early signs of rickets: 1, Head sweating and restless sleep; 2, loss of muscle tone; 3, polyuria; 4, pallor; and, 5, alteration in the bones of the skull. In the presence of any of these five symptoms, rickets should be suspected and the diet and hygienic conditions surrounding the infant should be investigated and the known factors of rachitis should be eliminated. No other disease responds so readily to appropriate treatment.

Proceedings of Societies

NEW YORK ACADEMY OF MEDICINE

SECTION IN GENITOURINARY SURGERY.

Meeting Held on March 15, 1922

DR. ABRAHAM HYMAN in the Chair.

Presentation of Case Reports (a) Steinach's Operation; (b) Two Cases of Gonorrheal Arthritis Treated by Nonspecific Proteins and Local Treatment.—Dr. LEO L. MICHEL presented these case reports. The former was that of a man who reported to the Hospital for Joint Diseases because of a severe, persistent pain in the lumbar portion of the spine. History and examination revealed a condition of marked neurasthenia and sexual impotence. Although numerous spermatozoa were found in the seminal fluid, they were immobile and apparently lifeless. The patient had already had treatment by electricity, mental stimulation, glandular extracts, etc., yet similar treatment was tried again at the hospital, but with no result. So a Steinach operation was performed at the hospital. Improvement was evident within six weeks after this operation. The backache had disappeared completely, there was no mental dejection, appetite was regained, the man became again sexually potent, and once more was able to attend to his work. The two cases of gonorrheal arthritis presented by Dr. Michel both received successful treatment, locally and intravenously, by injections of paratyphoid vaccine. The first was a typical case of chronic arthritis of the feet of gonorrheal origin which had been previously diagnosed as inflammatory rheumatism. After treating the focal infection locally for about two weeks without effect, injections of vaccine were added, beginning with fifty million, and repeating every four days, with the result that, with the sixth injection, all the joints were under control. The second case was one of acute arthritis of the shoulder and knee. Four injections were given, although the symptoms seemed to have been controlled after the second. Although the patient was discharged as well, he was still unable to have free use of his arm because of muscular atony.

Treatment of Acute Gonorrheal Urethritis With Acriflavine.—Dr. HOWARD S. JECK, who read this paper, stated that acriflavine was selected by Davis and Harrel as an ideal preparation for treating gonorrhea because of its marked penetrating properties, its nontoxicity within reasonable limits, and its definite germicidal properties in weak dilutions. Results from the use of acriflavine in treating gonorrhea, however, were not so remarkable as was hoped would be the case. Yet it seemed to produce better and quicker results than any other one remedy. The method of injecting the acriflavine, together with the quantity of saline injected, was of first importance in its successful use. Very small amounts should be slowly injected, rather than a quantity sufficient to cause overdistention, or even a small amount injected too rapidly. The latter seemed to produce harmful spasm of the urethra. A single daily anterior injection of one in five thousand solution retained for one half to one minute was sufficient to carry a case from the acute to the declining stage in a comparatively short time. Dr. Jeck said that in his experience cases treated with acriflavine alone ran a definitely shorter course than cases treated with other injections alone; and cases treated with acriflavine alone ran a shorter course than cases treated with acriflavine plus other injections.

Treatment of Acute Gonorrhea in Its Declining Stage.—This paper was read by invitation by Dr. HERBERT MOHAN; the first point discussed was the great difference between the time needed to bring the infection under control, and that given to its eradication. The paper dealt only with the long period of the declining stage. Little profit could be expected from the urethral use of any of the known disinfectants, but a better response was to be met with from mechanical measures, particularly the sound, and this instrument had, indeed, proved invaluable. Perhaps the tradition that instruments and gonococci do not go well together had accounted for the prejudice against its use. Experiments in passing the sound by very small degrees earlier and earlier in the course of the cure were made and resulted after a long while in the conclusion that the sound carefully passed did not result in a too troublesome exacerbation of the gonorrhea. Unfortunately, the cases so treated were not numerous enough to be imposing, and it might be argued that there was no way of proving that these patients might have been cured in the same length of time, had the sound not been used.

No untoward effect of this procedure was noticed, except a slight increase in the amount of discharge for about twenty-four hours, with a corresponding increase in the amount of pus in the urine. Improvement generally followed twenty-four or forty-eight hours after the passing of the first sound, which, in the cases under discussion, was never larger than a 22 F, and perhaps should have been smaller. Better results were obtained the earlier the sound was used, provided always the gonococcus had been first subdued. The day for mechanical interference could be set, not by time, but by clinical appearances. The usual time was four or five days, the patient having received daily injections or irrigations in the meantime. The earliest case of all those treated was of two days' duration. The first sound was passed on the third day, again on the sixth, and the patient was discharged on the thirteenth day. When seen four months later, he was still well. The greatest gain seemed to be obtained by passing the first sound when the urine was still hazy with pus. Increased rate of improvement was often negligible or absent if it was delayed until the urine was clear but shreddy. The most encouraging cases were those who most needed encouragement—patients of a long standing condition, whom every treatment seemed to help, but none to cure. Three such cases, with a constant discharge in spite of steady treatment, were noticeably helped at their first visit by the passage of a sound and an injection of acriflavine.

In treating posterior infections also, it appeared valuable to interfere while the lesions were still fresh and tender, and before they had settled down into chronicity. The first sound was passed, or the second or third, if necessary, only as far as the penoscrotal angle or bulb, the daily anterior injection was changed to a daily wash of the whole urethra for a day or two more, then the first sound was passed all the way. No disaster followed this instrumentation of the infected posterior urethra. In fact, the forced irrigation was regarded with a good deal more concern than was the sound, and for this reason a gentle method of carrying it out was adopted. In all cases it was done with a large plungerless syringe, the bulb of which was thin walled and soft. It was found better to irrigate before the sound than after, because the sound might bruise a lesion with the result that the fluid would be painful and bring about a spasm of the muscle.

The milder posterior cases progressed in the same manner as those with anterior infections. In all, only fifty-one cases were studied, and thirty-five had no interest for this paper, as there were no results, probably because the sound was withheld too long. The other sixteen showed at least a decided shortening of their courses as compared with earlier cases.

Treatment of Chronic Urethritis.—Dr. Edward L. Keyes, who read this paper, dwelt chiefly upon the importance of sexual hygiene in the treatment of prostatic inflammation, and emphasized the value of the use of the sound rather than that of the dilator for the cure of the most superficial lesions of chronic urethritis, both anterior and posterior.

Discussion.—Dr. Bierhoff said that in treating gonorrhea the first aim of the physician was to discover the gonococcus as soon as possible and destroy it. It made little difference what drug was used, so that it was not an astringent. When the acute stage had disappeared, the infection might remain; it was then the duty of the physician to locate the focus of this infection—to the urologist the two important sites were the anterior and the posterior urethra. Only after the gonococcus had been destroyed was it proper to use the sound. This should never be used if involvement of the prostate was suspected. It cases of chronic gonorrheal involvement of the urethra, it was a dangerous instrument and the dilator should be used instead. Neither instrument, he said, need be brutal in the hands of the right physician.

Dr. Lewis H. Marks reviewed in an interesting manner the theoretical foundation upon which Prof. Paul Ehrlich built up the preparation of acriflavine, which he discovered in his laboratory in Frankfurt during his investigations of African sleeping sickness.

Dr. Hardy reported on some work done by him at the City Hospital in treating gonorrheal arthritis and other infections with acriflavine, and stated that his conclusions agreed in the main with those of Dr. Michel.

Dr. Barringer said that he had been using this drug for about three years, and had found that about eight out of ten cases, if treated within the first four days after the appearance of the discharge, were helped. He asked if Dr. Jeck could throw some light on the patients that did not react promptly. The acriflavine seemed to irritate some, and not to clear up the urine, but to make it more purulent.

Dr. Morton stated that he had used acriflavine treatment in about twenty-five cases, and, from results received, was led to believe that it was perhaps the best method treatment yet in vogue. In the majority of cases, the results might be described as brilliant, conditions clearing up entirely in three weeks.

Dr. Ware took issue with Dr. Keyes on certain points in the discussion of acriflavine, and also gave some of his views on instrumentation.

Dr. L. T. Mann reported six cases treated with acriflavine by mouth, but the treatment was discontinued as productive of harmful results.

Dr. Aschner said that he was a follower of Bierhoff's method and used one half per cent. to one per cent protargol, ordering it every three or four hours. With this he had got results that he had been unable to equal with acriflavine. In cases of secondary infections he had had greater success with mercurochrome than with any other drug.

Dr. Asch emphasized the importance of exterminating the gonococcus as long as any trace remained, and Dr. J. J. Valentine spoke of his experience with the acriflavine treatment in France, and asked if there were any explanation of the varying results obtained from this treatment. Dr. Kaliski said that in his experience acriflavine should be regarded as "another" good remedy to be used in acute gonorrhea, but that it was not a cure at all. In some cases, especially early and first infections, it had little or no deterrent affect on the progress of the disease, and other remedies were to be substituted. Dr. Hyman stated that he also had found that in primary or first infections, acriflavine had not very satisfactory results, and that there were numerous recurrences. The good results were seen in those cases that had had previous infections. Whether this was due to the drug, or to the pathological changes in the urethra as a result of gonorrhea, could not be determined. He added that in cases in which the gonococcus was resistant to treatment, by irrigation, he had used the method described by Dr. Mohan, except that he had employed the dilator instead of the sound, and had had excellent results.

Meeting Held on April 19, 1922.

Dr. Abraham Hyman in the Chair.

A Presentation of Patients, Specimens, and Case Reports: (a) Demonstration of Desiccation, Coagulation, and Carbonization Tests with Soap, of the Oudin Current, by Dr. Victor C. Pedersen; (b) Hypernephroma of Kidney: Removal with Perirenal Fat en Masse, by Dr. A. Raymond Stevens; (c) 1. Papillary Carcinoma of Kidney: an Early Case; 2. Hydropyonephrosis Due to Calculus, Complicated by Resulting Fecal Fistula, by Dr. J. Sturdevant Read, by invitation.

Dr. Barney congratulated Dr. Read on being able to present such a specimen of renal calculus; he said that examination of recent literature showed that there was no example of renal fistula into the pleural cavity, the intestines, nor the stomach, whereas in former years there were quite a large number, showing that the diagnosis was now made sooner than it was twenty years ago. Such cases were almost unique nowadays.

Dr. Guy Hunner, of Baltimore, spoke, in connection with Dr. Stevens's case, of the bad prognosis in the ordinary case of hypernephroma, and the difficulty of early diagnosis.

Dr. Beer, referring to Dr. Pedersen's demonstration, said he had been greatly interested in trying to devise methods of more satisfactorily employing the D'Arsonval and Oudin currents; what had been bothering him most was the construction of an electrode that would render it possible to grasp the tumor, lift it, and then turn on the D'Arsonval current. He expressed the hope that some one would be ingenious enough to work out some such electrode.

Dr. Lowsley described a case of his own, a man who had had a large stone in the lower part of the right ureter. The man had seemed to be entirely well until within the two preceding weeks. A pyelogram disclosed the condition beautifully, and the distortions of the ureter were very distinct.

Dr. Aschner outlined one case he had seen of penetration of the bladder by the Oudin current. In reference to Dr. Read's case of pelvic neoplasm, he believed that primary complete nephrectomy was indicated.

Dr. Pedersen outlined two interesting cases of hypernephroma and requested opinions on the virulence of the disease. Dr. Beer raised the question as to whether the renal fat should be removed in all cases of kidney tumor. Dr. Hyman, replying to Dr. Pedersen, stated that at times it was impossible to prognosticate the course of hypernephroma, although it might be said that in general the prognosis was bad. A few cases had survived the operation two or three years and then died of metastases. Few patients surviving three years had at the time of the operation extension of the growth into the renal veins. Dr. Pedersen then discussed the D'Arsonval and Oudin currents, stating that the reason why the former was so much better than the latter was because the D'Arsonval, being a bipolar current, could be more fully controlled as to voltage, amperage, and heating qualities. This subject was followed by the discussion by several of those present of the arguments for and against the removal of perirenal fat.

The Question of Recurrent Calculi.—This very interesting paper was read by Dr. J. Dellinger Barney. He declared that there was an unfortunate paucity of investigation on the subject of recurrent or overlooked renal calculi, and that it would be desirable for various observers in different clinics to undertake such an investigation. Radiographic examination during or very shortly after convalescence was essential to the accuracy of the results in such a piece of work.

While the few data at hand showed that stones were subsequently found in the kidney after operation in a surprising number of instances, it was impossible to say which of these stones were "recurrences" and which "left overs." Actual recurrence was unquestionably very frequent.

The complex character of the interior of the kidney, hemorrhage from its mucosa, and the comparative inaccessibility of this organ in many cases contributed to the difficulties of removing all stones. Although various procedures might be resorted to for this purpose, none were infallible. It would appear that the fluoroscope offered the most promising prospects of success.

Preoperative study could not be too painstaking, nor must the possibility of superimposed shadows of calculi be overlooked. A second operation for the removal of remaining stones was advisable in most cases, and should be done soon after the first operation. Pyelotomy was unquestionably the operation of choice, and was often advantageously combined with partial nephrotomy.

Dr. Hunner said he hesitated to bring up his hobby of ureteral stricture after such a paper as Dr. Barney's, but his experience with this had been most illuminating on this subject of stone formation in both ureter and kidney—there seemed to be hardly any doubt that the majority of ureteral stones formed in the stricture area. Another important fact was that the stricture is so often multiple.

The discussion was continued by Dr. Beer, Dr. Rathbun, Dr. Pedersen, and Dr. Aschner, and closed by Dr. Barney.

Treatment of Metasyphilis According to the Method of Gennerich.—Theodor Brunner (*Schweizerische medizinische Wochenschrift,* August 17, 1922) reports on the effects of the following course of treatment; general treatment with uniform courses of eight to twelve injections of salvarsan given intravenously at intervals of five to seven days, with doses of 3 to 4.5 gram of sodium salvarsan at periods of 2.5 to 3.5 months. During this course of treatment, a course of iodine is given for six to eight weeks. During the intervals, a dose of three grams of sodium salvarsan is given intravenously every two to three weeks and also a course at Karlsbad for six weeks, in addition to the administration of abundant fluids. The intraspinal treatment with neosalvarsan is given at intervals of two to three weeks or, at the most, four weeks. Aside from occasional fever, vomiting and transient attacks of pain, there were no disturbances and the results were clinically striking in every case; parallel with the clinical improvement, there was a progressive diminution in the spinal fluid values, a regression of the Wassermann reaction and of the albumin values and also of the pleocytosis.

Clinically, the treatment resulted in a diminution of the severe cerebral disorders, a diminution of the psychomotor excitement, a return of memory and orientation and a disappearance of the disturbances of speech and chirography; there were also a retrogression of tabetic symptoms and a general all around improvement; parallel with the clinical improvement, there was also evident an improvement in the pathological spinal fluid in the sense of a retrogression of the high Wassermann, albumin and lymphocyte values. In a certain percentage of the cases, improvements and even cures are accomplished. The early cases, namely the demented cases, are more suitable for this treatment than the agitated cases. If no improvement occurs after the third or fourth intraspinal treatment combined with the intravenous treatment, the entire treatment should be discontinued.

Abstracts from Current Literature

GENITOURINARY DISORDERS.

Recurrent Renal Calculi.—J. D. Barney (*Surgery, Gynecology, and Obstetrics,* December, 1922) asserts that there is an unfortunate paucity of investigation in the matter of recurrent or overlooked renal calculi and it would be desirable to have various observers in different clinics undertake such an investigation. Röntgenographic examination during or very shortly after convalescence is essential for the accuracy of the results in such a piece of work. While the few data which are at hand show that stones are subsequently found in the kidney after operation in a surprising number of instances, it is impossible to say which of these stones are recurrences and which are left overs. Actual recurrence is unquestionably very frequent. The complex character of the interior of the kidney, hemorrhage from its mucosa, and the comparative inaccessibility of this organ in many cases contribute to the difficulties in removing all stones. Although various procedures may be resorted to for this purpose, none is infallible. It would appear that the fluoroscope offers the most promising prospects for success. Preoperative study cannot be too painstaking, nor must the possibility of superimposed shadows of calculi be overlooked. A second operation for the removal of remaining stones is advisable in most cases and should be done soon after first operation. Pyelotomy is unquestionably the operation of choice and is often advantageously combined with partial nephrotomy.

Chronic Prostatitis in Men with Bladder Fistulæ.—Henrik Alapy (*Gyógyászat* (Medicine), July 10, 1921) says that, as outlined by Alapy eight years ago, epicystotomy is indicated in the second or third stage of prostatitis with accompanying cystitis which is not relieved by catheterization, and where prostatectomy cannot be performed because of involvement of the kidneys or other organs. The relief afforded by the fistula is only temporary in some cases, as a troublesome complication develops later, which is characterized by pain recurring in three to four months or even in a few weeks. Pain due to an inflamed cord or epididymitis, as well as all observable complications, are excluded from the picture. Pain is of an increasing character in cases with open drainage tubes (Pezzer's catheter). Severe pain is also prone to develop in cases with closed catheter at the time of opening it for the purpose of urination, the pain lasting at times for fifteen minutes. The intervals between urination become shorter with the pain growing in intensity. The same pain is complained of during defecation or passage of gas.

The diagnosis of this pain should not be confused with pyelonephritis, which is notably improved by continuous drainage. Cancer can also be eliminated. Examination of excised prostate glands showed a chronic inflammatory condition around the inner capsule. The capsule is extensively infiltrated with mononucleated or multinucleated round cells, the infiltrations following vessel and glandular tracts. These chronic inflammatory changes are found only in glands with old bladder fistulæ and always in the tissue connecting the adenoma with the inner capsule. The relief from pain following prostatectomy is astonishing. The reason for the localization of the inflammatory process in the tissue layer between adenoma and inner capsule, the hypersensibility of the bladder lining, as well as the astonishing relief from pain following prostatectomy, are questions, still unanswered, which require further investigation.

Transplant of Ureters.—Robert C. Coffey (*Surgery, Gynecology and Obstetrics,* May, 1921) gives the following conclusions in transplantation of the ureters into the large intestine in the absence of a functionating urinary bladder:

Transplantation of the ureter into the large intestine is the most essential procedure in operations requiring removal of the urinary bladder.

The principal force to be dealt with in implantation of a duct into the intestine is static intraintestinal pressure. The influence of static intraintestinal pressure in dilating an unprotected duct mouth was first mentioned and described before the Southern Surgical Association meeting, at Hot Springs, Va., in 1909, and before the American Medical Association meeting, at St. Louis, in 1910. Submucous implantation of the duct, for the purpose of reversing the force of static intraintestinal pressure and bringing it to bear on the side of the duct, was demonstrated in the same presentation, including the technique of the operation.

The essential mechanical principle necessary to the uniformly successful implantation of the ureter is that the ureter shall be made to run immediately under the loose mucous membrane for a distance, before entering the lumen of the intestine.

Renal Functional Tests and Their Value in Urological Medicine and Surgery.—Leo Buerger (*Medical Clinics of North America,* November, 1922) shows that the phenolsulphonephthalein test is of secondary importance in functional diagnosis because a low phenolsulphonephthalein output merely indicates the inability of the kidneys to excrete the dye at any given moment, and because it yields no information as to what the kidneys could be made to do, or whether the patient is not in a state of good functional equilibrium; renal deficiency may be present, even in the presence of a normal phenolsulphonephthalein test. With a very small dye output (zero to ten or fifteen per cent.) the associated blood chemistry and either the Ambard or the accommodative test should also be used. With a zero phenolsulphonephthalein and high blood values, the patient is in danger, but it is only when, in addition, the Ambard coefficient is high or the concentrating power is lost and the tests for accommodative activity are defective, that the patient is inoperable. When the blood chemistry is repeatedly normal with a minimal output of phenolsulphonephthalein, the Ambard coefficient or the test for concentrative power is an additional safeguard. Very high urea, total nitrogen, creatinin and uric acid values are positive evidence of renal inadequacy. Very high uric acid and creatinin values always suggest the presence of chronic nephritis upon which a surgical lesion may be engrafted or an acute nephritis superseding the surgical lesion. In fact, none of the tests can be accepted at their face value unless they are checked up and confirmed by the other important methods of testing.

In urological surgery, the phenolsulphonephthalein test may be used: 1, for a rapid determination of the combined total function of both kidneys, for the rapid differentiation between two kidneys and for the recognition of the diseased kidney; 2, for the determination of the blood values in the diagnosis of chronic nephritis for the estimation of the severity of the prognosis and for the determination of the retention of waste products; 3, the Ambard coefficient or MacLean index should be used as a valuable adjunct to both the phenolsulphonephthalein test and the blood chemistry; and 4, one of the two hour tests, that is, tests for the accommodative or concentrating power of the kidneys, either the Schlayer-Hedinger, the two hour renal test and the Mosenthal modification of the Strauss test. In most cases, where the blood chemistry is repeatedly normal, the phenolsulphonephthalein test normal and nephritis absent, the urea being adequate and the specific gravity normal or near normal, a nephrectomy may be done without recourse to the other tests. But in bilateral renal disease, the haphazard acceptance of an occasional phenolsulphonephthalein test and an occasional estimation of urea nitrogen, total nitrogen, creatinin and uric acid may not suffice and may even be misleading. Urologists with limited experience should also make use of the Ambard coefficient or the MacLean index, supplemented by tests for concentrative power and accommodative response as an additional safeguard.

Bladder Neck Obstruction.—W. B. Parker (*Surgery, Gynecology and Obstetrics,* January, 1923) gives the following summary:

1. That due to recent research on living patients with definite clinical entities of bladder neck obstructions, and not upon necropsies of those with advanced types of obstruction; more attention to diagnosis and relief forces a conclusion that posterior median bars exclusive of the Albarran type of hypertrophy are not so common as generally believed, and that a widely contracted bladder neck will be found a most common cause in the fourth and fifth decades for progressive vesical irritability and retention, that the causative influences are often not only local infections, but remote foci and systematic toxemias.

2. That the method of choice for classical contractures of the bladder neck of all types requiring major relief are best approached by the MacGowan modification of Young's technic, either suprapubically or through external urethrotomy incisions, for the educated finger is far superior to poor light illumination and to the same touch through an instrument intraurethrally in determining the removing of scar tissue to the level of resilient muscle, so that one may know the floor of the bladder again to be level with the floor of the urethra. Further, the operator may rest assured that the greatest of all dangers following this type of surgery—hemorrhage—is easily prevented and controlled.

3. That the modified Young punch or median bar excisor is to date the most efficient and safe instrument that is not limited in its field, for surgical relief of the bladder neck, associated with prostatic atrophy, prostatic hyperplasia, vesical calculi, or hypertrophied trigone.

4. That it is a most valuable aid, preceding, during, and following prostatic enucleation for incising the bladder neck and trigonal shelf, removing capsular tags, and small portions of prostatic tissue that are difficult of immobilization.

5. That a more satisfactory explanation is yet to be advanced as to bladder neck tone and the etiology of irritability, hypertension, spasm, and tenesmus, in reference to the production of contractures of the mechanical type.

6. That the mortality rate has been nil, that hemorrhage, although all former precautions were employed, has not occurred in bladder neck obstruction relieved by use of the modified Young punch; that postoperative absorption is less, and convalescence is shortened. Epididymitis in males past the procreative age is prevented by vasectomy. Last, but not least, the preparation of the patient for any type of major bladder neck surgery is of the utmost importance.

Diagnosis and Treatment of Ureteral Calculi.—Kenneth M. Walker (*Clinical Journal,* August 30, 1922) says that when the radiogram shows a calculus no larger than a large orange pip, and the kidney reveals no evidence of sepsis or back pressure, expectant treatment should be advised. The patient should be encouraged to drink copiously of bland liquids, to take plenty of exercise, and to await the passage of the stone by the ordinary channel. Fresh radiograms should be taken at monthly intervals and a record thus kept of the progress of the stone. If no alteration is noted in the position of the stone at the end of six months, more energetic treatment is needed; if it has moved, patience should still be exercised. The first of the energetic methods to be used is the dilatation of the ureter below the calculus by means of the passage of a ureteral catheter or bougie. If the catheter can be passed beyond the calculus, the prospect of success by such a method is excellent, but even when the tip of the catheter sticks at the level of the calculus, success is by no means out of the question. A catheter in the ureter acts in the same way as a catheter tied into the urethra. It produces muscular relaxation and dilatation of the canal. This dilatation is often sufficient to allow of upward passage of the calculus. When withdrawing the catheter the friction between it and the calculus is often sufficient to drag the latter a certain distance down the ureter. In order to achieve success the process may have to be repeated on several occasions, but as long as progress is made the method should be persevered with.

An additional help to the progress of the stone is lent by injecting a lubricating material, such as sterilized olive oil, into the urethra below the level of the stone at the moment of withdrawal. A two per cent. solution of papaverine sulphate, which has the property of relaxing the unstriped muscle fibres, may be injected into the ureter before removing the catheter. It must be admitted that a certain danger exists in leaving the catheter in the ureter longer than a few hours, and, especially when sepsis is already present, it is wise to inject a little saline through the catheter before removing it.

When the progress of the calculus into the bladder is prevented by the narrowness of the ureteral orifice, the latter must be enlarged, either by dilatation or incision. This is carried out through an operating cystoscope. Dilatation may be effected by means of suitable forceps, or else by employing a laminaria tent. This is placed in position within the ureteral orifice by means of a somewhat ingenious artifice. The end of an ordinary ureteral catheter is cut off, and the central wire made to protrude half an inch. On this is threaded a fine laminaria tent of a calibre equal to that of the catheter. Thus mounted and forming a tip to the catheter the laminaria tent may be inserted into the ureteral opening. It is set free by simply withdrawing the wire obturator of the catheter, and is left in the ureteral orifice until dilatation has occurred. At the end of three or four hours the tent is removed by means of a thread attached to its lower extremity, and passing out through the urethra. When these methods have failed or there is evidence of sepsis or back pressure, an open operation is indicated.

A Simple Reaction for the Demonstration of Infected Urinary Passages.—Oskar Weltmann (*Wiener klinische Wochenschrift,* August 10, 1922) checked up the results of the Griess test and reports that positive reactions in freshly passed urine are a reliable sign of infection of the urinary tract. This is a simple test for bacterial activity in the urinary tract, as nitrites are not formed in the urine except from bacterial activity. In the Griess test (Ylosvary modification), a half gram of sulphanilic acid is dissolved in 150 c. c. of dilute acetic acid (solution I); 0.2 gm. of solid a-naphthylamin is heated in 20 c. c. of distilled water and the colorless solution poured off from the blue residue is mixed with 150 c. c. of dilute acetic acid (solution II). The two solutions are mixed to form the reagent, which is kept in a bottle with a tightly fitting glass stopper. The cherry red discoloration shows a positive reaction.

Diastase Reaction of the Urine.—Arthur F. Sladden (*Lancet,* July 8, 1922) advocates an improvement in the Wohlgemuth technic, emphasizing the fact that the hydrogen ion concentration (pH) is not a negligible factor in the technic, especially when measuring quantities of diastase at the lower levels, as in cases of renal insufficiency. Pyelitis and pyelonephritis of definite bacterial etiology have no effect on the diastase output. If such a nephritis shows a progressively decreasing diastase content, the indication is serious; the increase of diastase in the convalescent stage of acute nephritis is strikingly in accord with the clinical improvement. In inflammatory conditions of the pancreas, a high diastatic value is the rule, and in the presence of a low diastase excretion tumor or atrophy rather than inflammation should be suspected. Many diabetics show a definite increase in total diastase units excreted in twenty-four hours. This test is most valuable in the differentiation of toxemia of pregnancy from pyelitis or nephritis in pregnancy: a sharp fall in the number of diastase units after two days is an indication for evacuation of the uterus. The urine tested should have a standard hydrogen ion concentration, preferably pH 6.7. The total day's excretion, rather than the unit value alone, should be considered.

Treatment of Ulcer of Bladder. — H. L. Kretschmer (*Surgery, Gynecology, and Obstetrics,* December, 1922) contends that the consensus of opinion among urologists is that this is a surgical condition and that once the diagnosis is made, nothing short of an operation will suffice. Indeed, it is the last choice as far as our therapeutic agents are concerned, since the majority of these patients have had all sorts of local treatment, the only result of which seems to be an aggravation of symptoms. Wide resection of the ulcer bearing area is the only treatment that has been carried out in this series with the exception of two cases which were treated by fulguration. In one case fulguration had been instituted elsewhere, and although most authors condemn this form of treatment, yet the result in this case (perhaps temporary) was rather striking, as brief résumé of patient's history shows. Of the eight patients operated upon, one had a relapse and another had pus and staphylococci in the urine. The remaining patients consider themselves well; that is, they are free of symptoms. Two patients were treated by fulguration with an immediate relief of symptoms. Time only will tell whether this will be permanent. Of the remaining four patients, two are no longer under observation and the other two have shown an improvement in their condition, this without any treatment. However, these two cases are not entirely free of symptoms.

Stalagmometric Investigations on Urines.—Kj. v. Oettingen (*Zentralblatt für Gynäkologie,* July 15, 1922) states that stalagmometry, which is the determination of the surface tension by the number and size of the drops, when the urine flows out of a fine cannula with the Traube apparatus, may be used as an adjunct to clinical diagnostic analysis. The urine is acidified previous to the determination and the resulting acidity quotient of the urine is found to be increased in pregnancy, infectious diseases, and malignant tumors. The most significant finding is the increase of the acidity quotient in the early diagnosis of pregnancy. The substances which lead to the changes in the surface tension are designated as stalagmones—the catabolic products of albumin bodies. The diseases with a diminished surface tension in the urine show conditions in which an increased cellular destruction occurs and there is an extensive parallelism between the acidity quotient in the urine and the changes in the blood, recognizable by the accelerated sedimentation of the red blood cells or by an increase of the lability of the plasma.

Tying off the Ureter.—Fritz Bierende (*Zentralblatt für Gynäkologie,* July 15, 1922) reports a case of partial atresia of the vagina with partial hematocolpos, hematometra and hematosalpinx. During the course of the laparatomy, the right ureter was divided at its upper portion. Inasmuch as an implantation of the ureter into the bladder was impossible, the ureter was dissected free at its upper part and two ligatures were superimposed on each other at the stump and another ligature was applied below. The ureteral stump was buried at the upper part of the wound. Recovery followed. Experimental ligation of the ureter has been found to result in dilatation of the renal pelvis and more or less marked hydronephrosis with secondary and gradual atrophy of the renal tissue and its replacement by connective tissue, so that the final result is the formation of a hydronephrotic sac with a thinned out atrophic wall. In the case reported there was also a severe infection of the hydronephrotic sac. This infection does not always occur.

The Mechanism of the Elimination of Phenolsulphonephthalein by the Kidney—A Proof of Secretion by the Convoluted Tubules.—E. K. Marshall, Jr., and J. L. Vickers (*Bulletin of the Johns Hopkins Hospital,* January, 1923) report experiments on dogs which lead them to the conclusion that the elimination of phenolsulphonephthalein by the kidney cannot be explained entirely on a filtration and reabsorption theory, but that the addition of a process of secretion of the substance by the convoluted tubules is necessary.

Obstruction of the Ureter.—C. A. Hill (*International Journal of Surgery,* December, 1922), in considering obstruction of the ureter as a frequent predisposing cause of localization of bacteria in the pelvis of the kidney, concludes as follows: 1. Obstruction of the ureter without infection, but with lowered resistance, is more often present than has generally been surmised. 2. This condition is a predisposing cause of pyelitis and pyelonephritis. 3. Certain organisms, as the colon bacillus, have a predilection for the upper urinary tract. 4. Routine urine culture is a valuable addition to the diagnostic armamentarium of the surgeon. 5. Early recognition and treatment of obstruction is highly desirable, for the long standing cases are often incurable with measures in use at present. 6. Every gynecologist should be thoroughly familiar with the cystoscope for diagnosis and treatment or, at least, should be able to provide facilities for its use.

DISEASES OF THE EAR.

Acute Suppuration of the Middle Ear: Early Drainage of the Mastoid Region—Being dissatisfied with the results from mere paracentesis and instillations into the external ear, Dan McKenzie (*Lancet,* June 17, 1922) tried the effect of early drainage of the antrum with satisfactory results in cases in which the acute symptoms disappear after the onset of the discharge, but the discharge persists in spite of meatal treatment. Until the discharge ceases, the patient is in danger of losing both his hearing and his life. Early postauricular opening of the antrum and mastoid cells obviates these dangers. The time for operation varies according to the individual case, but the author prefers not to postpone it longer than ten days after the rupture or the incision of the membrane; it has, however, been done as late as six weeks to three months after the onset of the discharge. The longer the delay the less the chance of success. A purulent discharge indicates septic infection in and about the middle ear and it should be cut short as soon as possible.

On draining the antrum the author came upon all stages of the disease from hyperemia to the purulent and semipurulent stage. Usually the antrum or mastoid cells contain a glairy, blood stained, mucoid material and the rupture of the membrane was usually imminent. If the antrum is opened prior to the rupture of the membrane, paracentesis is usually indicated at the same time. Cases not cured shortly after the rupture or incision of the membrane often show pus in the antrum and mastoid cells and even granulations, but no classical signs of mastoid suppuration, except tenderness on pressure. The usual postaural incision is made, the mastoid is opened with gouge or chisel and all of the cells are exposed and cleared out; the antrum is freely opened up. The bone cavity is then rubbed with bipp, a gauze drain is inserted to the antrum and the rest of the wound is sutured. A dry dressing is applied for twenty-four hours but after that fomentations are applied. A small drainage tube is better than gauze. When the discharge becomes serous the wound is allowed to close. The middle ear is not interfered with except when paracentesis is done and the membranous and bony meati are left intact. The results are gratifying: the discharge from the middle ear stops immediately after the operation and the membrane undergoes complete healing, leaving no perforation and hearing is restored. In case of reinfection of the middle ear after an apparent cure, the pus works its way out through the mastoid process as a subcutaneous abscess under the postaural scar, making the reopening of the wound unnecessary.

Treatment of Aural Sepsis in Adults.—William Stuart-Low (*Practitioner,* October, 1922) says that the following rules, if thoroughly carried out by doctor and patient, will not only almost certainly relieve, but in ninety per cent. of the cases cure the condition: Never syringe the ear in acute or subacute cases, and practically never in chronic cases. When masses of hard cerumen coexist with aural sepsis, it may be necessary to irrigate very gently with warm antiseptic lotion, but always instil spirit drops immediately afterwards. Never use peroxide of hydrogen or oxydol as drops in the ear; they are feeble antiseptics, and only serve to spread the sepsis further afield. Wipe out the meatus and tympanic cavity frequently with aseptic wool on probes, and then insert antiseptic drops. Never allow wool in the ear. Daily Politzerize and suck out the ear with Seigel's pneumatic suction apparatus, and immediately afterwards mop up all discharge with wool on probes. Always see to the asepsis of the nose, mouth, and throat, and the removal of nasal obstructions in every shape and form. Enlarged tonsils and adenoids should be operated upon, and all pyorrhea alveolaris and dental caries attended to punctiliously. Make every endeavor to improve the patient's general health so as to raise the resistive power of the blood and reinforce its bactericidal qualities. See that the patient is in the open air night and day as much as possible, and that fresh uncooked food is taken liberally. Change of air to the sea is always advisable, the patient being specially instructed how to maintain the cleanliness of the ear while away. Sea bathing should be prohibited. Keep the hair back off the ears. This is most important, for the hair over the ears, impedes the aeration of the ear, and microbes gain entrance from the hair and scalp. When the scalp is very scaly, indicating the presence of seborrhea due to cocci in the hair and surface of the cuticle, the cocci fall into the ear and serve to keep up the discharge.

DERMATOLOGY.

Treatment of Psoriasis by Manganese.—James Moore (*British Medical Journal,* July 8, 1922) reports very good results in thirty-five cases of psoriasis. His conclusions are as follows: 1. Although psoriasis appears to be of spirochetal origin, neither any of the arsphenamine preparations nor mercury has any beneficial action on it. 2. Mixed staphylococcic vaccine improves the lesions, but does not make them disappear completely without the use of chrysophanic ointment. 3. Collosol manganese clears up the disease after six to sixteen intramuscular injections without any external application. 4. Owing to the favorable action of staphylacoccic vaccine and especially colosol manganese, psoriasis is probably caused by a special staphylococcus, or it is at least closely related to chronic staphylococcus infection. 5. The disease is autoinoculable. 6. The familial occurrence of psoriasis is probably due to living under the same conditions and the subjection to the same infection rather than to heredity.

Treatment and Prognosis of Leprosy.—P. Harper (*British Medical Journal,* July 8, 1922) states that the general measures in the treatment of leprosy include, 1, regular meals of abundant food; 2, an open air life; 3, gentle exercise and daily baths, and 4, a happy frame of mind, encouraged by kindly personal interest, plenty of amusement and remunerative work. Because of its low infectivity, leprosy is an ideal disease for home treatment. The septic infections are amenable to simple surgical measures: perforating ulcers over chronic adventitious bursæ should be excised with the bursæ. The neuritis is treated by cutting down on the nerve throughout the extent of the enlargement of the nerve and by pulling the epineurium from the inflamed nerve. Rhinitis is improved with irrigation given twice daily and packing with sterile gauze. The iritis is treated in the usual manner. The specific treatment recommended by the author is the intravenous injection of crude chaulmoogra oil, sterilized by heat, giving five to fifteen minims of the oil at body temperature one to three times daily. A fortnight's rest is given after four weeks' injections and the treatment is then continued until a reaction occurs, when the treatment is stopped until the reaction has passed. The treatment reaction consists of fever, eruption and neuritis markedly resembling the true leprotic fever, followed by improvement. The treatment must be continued for years. Early and mild cases have a fair chance of cure or arrest of the disease. Pure nerve leprosies have been arrested. The advanced nodular cases or those with marked nerve deformity are incurable. In many cases, leprosy seems to prolong life, possibly as a result of the careful mode of life, and death usually results from an intercurrent disease, chiefly tuberculosis and sepsis.

The Action of Flavine Antiseptics on Localized Pyogenic Infections, With Special Reference to the Processes of Healing.—C. Bennett, J. W. Blacklock and C. H. Browning (*British Medical Journal,* August 19, 1922) in over six hundred cases, including burns, ulcers of the leg, carbuncles, cellulitides, osteomyleitides, acute suppurative bursitides, abscesses, septic hands and fistulas in ano, found that the results from continuous treatment with flavine antiseptics (acriflavine and proflavine) in comparison with other methods of treatment, showed no interference with the formation of granulation tissue. The points especially investigated were those of the rate and progress of the formation of granulation tissue, of ossification and of the healing of the skin epithelium. There was no evidence of pellicle formation or necrosis. There was no unusual tendency to hemorrhage, more than occurs ordinarily with healthy granulations during a change of dressings. Ossification proceeded actively in periosteal granulation tissue. Epithelial regeneration proceeded actively in contact with dressings soaked in flavine solution. The histological examinations confirmed and supplemented the clinical observations.

Technical Fundamental Principles in the Use of Dermographism as a Method of Examining Bloodvessels of the Skin.—Leonard Schwartz (*Schweizerische medizinische Wochenschrift,* August 17 and 24, 1922) devised a simple and handy apparatus for the production of skin reactions. If a symmetrically favorable area of skin (on the chest) is selected, and if the period of latency between the irritation and the appearance of the dermographic reaction is determined, both as to intensity and as to duration, it is possible to obtain a series of similar reactions, so that the subsequent investigations regarding the effect of any desired agent on the bloodvessels of the skin may be possible.

Familial and Constitutional Polycythemia Rubra.—Hans Curschmann (*Acta Medica Scandinavica,* November 29, 1922) finds no proof of the supposedly frequent endocrine anomalies in his three cases of familial polyglobulia and one nonfamilial, although a constitutional case of this disease. Endocrine disturbances are rarely found as symptoms in polyglobulia. Familial polyglobulia and cases beginning in early childhood and remaining latent for as long as ten years are not infrequently met with. The endocrine system plays no rôle in this disease.

A Few Points Regarding the Diagnosis and Treatment of Gallbladder Lesions*

By MAX EINHORN, M.D.,

New York.

Soon after the appearance of the duodenal tube, it was quite natural to examine the duodenal contents in affections of the organs contributing toward its formation. In 1914 I published a paper (1) relating to this subject. This paper was followed by several others showing the importance of the direct examination of the bile in the fasting condition of patients suffering from gallbladder disease, for under those conditions pure bile could be obtained without the admixture of food or much gastric secretion. It was found that in normal persons the bile appeared golden yellow and was either perfectly clear or only slightly, if at all, turbid. In patients affected with stone or severe gallbladder lesions, the bile was found to be turbid, often having the appearance of yellow or greenish pea soup. Microscopically, numerous cholesterin or calcium bilirubin crystals, pus cells, mucus, bacteria, and occasionally a few red blood cells were found; and at times in the aspirated bile sample minute particles of concretions or mucus containing some solid material of pinhead size were discovered. On putting these under the microscope, conglomerations of various crystals would be observed. Often such findings indicated the probable presence of a stone, which upon operation was found to be correct. While a few crystals of cholesterin found here and there in the bile is not necessarily indicative of stone, if a great many of these are found clustered together, especially of large size, it usually indicates the presence of calculus.

The bile found in the duodenum usually contains bile from the liver mixed with some gallbladder bile. Attempts to obtain pure gallbladder bile or the segregation of liver bile and gallbladder bile have been made by Stepp (2) and later by Lyon (3).

I may here be permitted to give in a few words the origin of the belief that gallbladder bile as such can be obtained. Rost (4) did a great deal of experimental work on animals into which he had introduced a tube through a duodenal fistula. Originally he intended to study the action of various medications as bile stimulants (cholagogues). He observed that peptone (Witte's) when introduced into the duodenum led, after a few minutes, to the appearance through the tube of an abundant flow of dark bile. In animals, however, in which the gallbladder had been removed, this did not occur. He ascribed this phenomenon to the action of the peptone on the gallbladder causing a contraction of the latter and the emptying of its contents. This explanation appeared to be plausible, since the gallbladder is supposed to have the faculty of concentrating the bile. Stepp made use of these experiments and applied the same principle to the direct examination of the bile in man. He therefore injected into the duodenum five per cent. of the same solution of peptone (thirty c. c.) and soon noticed that here, too, a few minutes after the injection, an abundant flow of bile resulted, having also a very dark brown color, the flow lasting for several minutes, when a change of color took place. He therefore thought, like Rost, that the dark bile originates from the gallbladder, ascribing it to an emptying of this organ.

Meltzer (5) suggested the use of magnesium sulphate through the duodenal tube in order to relax the sphincter of Oddi, and to produce an emptying of the gallbladder, following the law of contrary innervation.

Lyon made use of Meltzer's proposition, and applied the magnesium sulphate to the direct examination of the bile in man, and came to the conclusion that it was possible to segregate the bile from its different sources, which he named a, b, and c bile, b indicating the dark gallbladder bile, and he must be given the credit for having promulgated this method of diagnosis and treatment.

The view, however, that the dark bile appearing after the instillation of magnesium sulphate or peptone is merely gallbladder bile, is not correct. In a paper (6) read before the Clinical Society of the Lenox Hill Hospital on December 10, 1920, I set forth a number of facts which do not seem to tally

---

*Read before the Atlantic County Medical Society on January 12, 1923, at Atlantic City, N. J. (From the Lenox Hill Hospital.)

Copyright, 1923, by A. R. Elliott Publishing Company.

with the accepted view of Lyon and Stepp. The reasons why the theory of the dark bile emanating from the gallbladder cannot be sustained are the following:

1. If one follows the variations in color of the duodenal contents after the introduction of magnesium sulphate or peptone, it will be observed that the change from yellow to dark brown does not take place abruptly, but rather gradually; at first the contents appear light yellow, then they show a deeper yellow, then brown, and ultimately a dark brown color. This color reaction lasts a few minutes, when a gradual reverse or a diminution of the color reaction takes place. Neither does the change of color at this time occur suddenly, but it forms a gradual mutation of colors from dark brown to light brown, yellow, and golden yellow. If the dark colored bile were due to an emptying of the gallbladder the change would appear and end more abruptly.

2. Magnesium sulphate given in different strengths produces different degrees of color reactions. That means that a twenty-five per cent. solution of magnesium sulphate produces a much darker bile than a ten per cent. solution. This likewise could not be the case if the dark bile was due to an emptying of the gallbladder, because the bile from the gallbladder must always look the same.

3. The specific gravity of the dark bile obtained after magnesium sulphate instillation is much higher than that obtained after a peptone instillation. This, again, would not be possible if the substances injected acted merely as openers of the gallbladder.

4. A great many other salts besides magnesium sulphate, such as sodium sulphate, and others, act in a similar way, producing dark colored bile. Meltzer's theory of the mechanism opening the sphincter of Oddi could not explain why sodium sulphate, which has no effect on the sphincter, could produce dark bile.

5. Soon after having emptied the gallbladder through magnesium sulphate or having accomplished a cycle of bile, another instillation of magnesium sulphate or peptone in some instances produces another cycle of color reaction, exactly the same as the first. This would hardly be possible if the dark colored bile were due to an emptying of the gallbladder, because then the second injection could not immediately produce a second emptying, the gallbladder being empty already.

6. Patients whose gallbladders have been removed, frequently show similar reactions after magnesium sulphate or peptone instillation, clearly showing that the gallbladder, as such, can have nothing to do with this phenomenon of color changes in the bile.

It appears to me, therefore, that these changes are due to reactions of these different substances on the liver, influencing its activity and thus producing the mutations in color.

When I was in Carlsbad last summer, Professor Stepp asked me how I could explain Rost's experiments, and since then I have taken pains to peruse carefully the entire series of Rost's experimental work, reaching the conclusion that while his experiments are all correct, his deductions could be differently explained. Thus, he found that in some animals in which the gallbladder had been removed, there was, after the lapse of a few months, a return of dark bile. In some of these animals he found upon autopsy that a new gallbladder had formed; in others, however, there was no gallbladder present, and still the dark bile had existed during life after the peptone injections. Rost, instead of saying that the peptone acted on the liver—since in these cases there was no bladder which could contract—assumes that the bile must have been kept back in the bile ducts of the liver and there assumed the dark color. This, however, is not plausible, for there is no reason for bile to be concentrated in the bile ducts. The reason why in some of the cholectomized animals there was soon after the operation no dark bile reaction following peptone instillation is that the operation, as such, acts as a disturbing factor on the liver, in this way diminishing its functional activity.

Recently a great many other clinicians have likewire refuted Lyon's and Stepp's theory (*7*).

X ray examinations are certainly of great value in the diagnosis of some affections of the gallbladder, especially if these are complicated with stones. It is, however, well to remember that a great many biliary calculi do not appear on the plate. Again, in exceptional cases, shadows are seen resembling biliary calculi which operation fails to substantiate. Notwithstanding this, I consider this means of diagnosing the presence of calculi as of the greatest importance.

As is well known, acute attacks of upper abdominal colic, with intervals of euphoria, are characteristic of gallbladder trouble. There are, however, cases which run an entirely different course. Local symptoms may be present or may be entirely missing, while there exist reflex disturbances which can be ascribed to the gallbladder lesions. Among these may be considered of importance the following types of disturbance: Migraine and bilious vomiting; angina pectoris; cardiospasm, and intestinal obstruction.

1. Severe migraine with bilious vomiting is occasionally caused by gallbladder trouble with or without stones. As an instance of this type, the following case may be briefly described:

Case I.—Mrs. J. H. suffered for many years with severe attacks of migraine occurring every two or three months, accompanied by vomiting and lasting for two or three days. Upon examination a condition of enteroptosis and movable kidney was found. A supporting abdominal bandage was applied and a general régime to build up the system was instituted, with fairly good results. The migraine, however, persisted, although occurring less frequently. About five or six years ago an x ray examination of the gallbladder region showed stones to be present; a direct examination of the bile likewise furnished all the signs of severe cholecystitis, with probable stones. The patient was operated upon and the gallbladder and stones removed. Since then the patient has remained entirely free from migraine.

2. Occasionally it is difficult to decide whether an attack of upper abdominal colic accompanied by a feeling of constriction in the chest and perhaps embarrassment of breathing is due to a circulatory disturbance (angina pectoris) or to a gallbladder lesion. A correct diagnosis in such a condition is of great importance for the patient: for while a circulatory disturbance can be handled with great difficulty and

is likely to interfere with the patient's mode of life, without any bright prospects for the future, the other (the gallbladder condition) is much easier to manage and can often be entirely cured. Whenever a condition of angina pectoris is found in a comparatively young man—say from thirty to fifty—in whom there is a mere suspicion of the presence of a gallbladder lesion, the case should be thoroughly investigated, and if any points are found corroborating such a condition the treatment should be arranged accordingly. Recently, I have observed two cases of this type. In one, the diagnosis of angina pectoris had been made by the best New York clinicians. The patient could hardly attend to his business and had to lead a very restricted life; but when a diagnosis of gallbladder lesion was made through the direct examination of the bile, an operation for the removal of the gallbladder and several calculi was performed, and the entire situation was changed. The patient is now able to do anything he wishes. Another patient with a similar disease complex (angina pectoris), manifested jaundice in one of his attacks, which helped to simplify the diagnosis of gallbladder lesion with probable obstruction of the common duct. The patient was operated upon, and the gallbladder was found to be much diseased and constricted, but no stones were present.

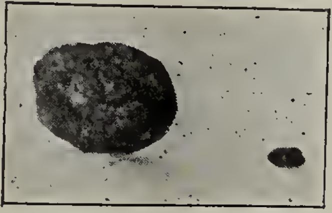

Fig. 1—J. A. G. Stone found in cystic duct at operation on October 30, 1922. The small particle to the left shows one of the many concretions which emptied from the common duct. One half times natural size.

Here I would like to emphasize that at times the diagnosis of a biliary calculus appears to be quite certain and yet a stone may be absent, the symptoms being due only to the gallbladder itself. It is important to remember this so as to be able to advise the patient accordingly.

3. Cardiospasm or dysphagia due to cardiospasm as a reflex of gallbladder trouble is not an uncommon occurrence. One patient, J. B., in whom a cardiospasm was discovered shortly before a gallbladder operation (the patient being unable to swallow or eat) was entirely cured after the removal of the gallbladder.

4. General tympanites and vomiting, accompanied by a rise of temperature, simulating intestinal obstruction, may be due to a gallbladder lesion. Dr. Willy Meyer and I observed a case of this sort, in which the removal of the gallbladder, with stones, relieved the condition.

As an illustration of the great importance of the history and the direct examination of the bile, in making a diagnosis, the following case may be cited, which came under my observation recently. I give the history as written by the patient himself:

Case II.—J. A. G., aged forty-one, "a moderate smoker and drinker. To the age of fourteen years, was always very strong, but suffered from severe headaches at school. Started work at fourteen years in a quarry office, articled to an architect; served as an engineer on tunnels in London, and as a civil engineer in Malta on sea work. After 1907 was for some years in Canada in charge of open air construction work, getting plenty of exercise. After 1915 started in business for himself, exercise being curtailed thereby. Had always held positions of trust and responsibility, at times involving considerable mental strain.

"At nineteen or twenty years of age, while in London, was very liverish and suffered from continued deep depression. At twenty-four, in Malta, had some jaundice. In Canada, was very liverish at times and subject to fits of depression. Have suffered from severe headaches and pain in back for last eight or nine years. Generally healthy, below par, but lost practically no time from business until 1916, when at the age of thirty-six had a nervous breakdown, stomach and eyes being affected. When recovered, still continued to have stomach acidity, headaches, and depression.

"In 1922 suffered from continued acidity, lack of appetite and considerable lack of energy. In July, August, and on the 13th of October, suffered from severe pain in the right side, which was ascribed to indigestion. Two days after the attack of pain in October, jaundice developed, which cleared up at the end of ten days. Pain in the right side almost continuous ever since the October attack. Urine very light brown from October 13th to November 1st. Was in bed from October 13th to October 30th; but continued on liquid diet, no fat, from October 13th to November 20th. Since then, kept on solid diet with no fat.

"Pains are on right side, about the last rib, start very mildly and become intense in from three to six hours. Pain radiates to left and to back up to shoulder blade; practically always stops suddenly, leaving a feeling of exhaustion. Pains start at all times, but seldom during the night. Have not had to take morphine, or other drugs. Position of body does not influence pain. Since about November 20th, have greatly improved in general condition, and acidity practically not existent. Bowels always very regular. Only medicine taken has been a mineral water and a few doses of liquid petrolatum."

Report of x ray examination, October 30, 1922. "Gallbladder region does not show the presence of gall stones."

November 1, 1922: "X ray examination of gastrointestinal tract suggests the presence of a duodenal lesion. Stomach is small, regular in outline, hypertonic, active; no tenderness present. Duodenum fills indistinctly; at one and a half hours about one quarter of meal is present in the stomach. At three hours the stomach is empty and head of column is at the splenic flexure. At six hours, greater portion of meal is in the large bowel, there being little change in the advance. At twenty-four hours, practically the entire meal has passed." W. A. Wilkins, röntgenologist Montreal General Hospital.

When I examined patient the gastric contents showed a condition of hyperchlorhydria, and the string test showed a blood stain at twenty-three inches from the lips. The bile was turbid, containing pus corpuscles and calcium bilirubin crystals. In the duodenal contents, which were turbid, a blackish looking particle of pinhead size was found, which upon microscopic examination proved to consist principally of debris and calcium bilirubin crystals. A diagnosis was made of duodenal ulcer combined with gallbladder trouble (probably stone in the cystic duct). The patient was first treated with duodenal alimentation in order to cure the ulcer, and then an operation was advised for the gallbladder condition. Dr. Willy Meyer operated upon the patient. The gallbladder was not adherent, and to outward appearance it was almost normal. On palpating it the surgeon at first had difficulty in discovering anything wrong, but on further search a concretion was detected in the cystic duct, and on removing the gallbladder a solitary black stone was found in the cystic duct (Fig. 1), while many small concretions were discovered, when the common duct was incised. When the gallbladder was opened the bile was dark and putrid. Here the history combined with the examination of the bile cleared up the diagnosis.

TREATMENT.

The treatment of gallbladder lesions may be either medical or surgical, or both. As a general rule, however, I would say that whenever feasible all cases should be treated medically only, unless there are sufficient reasons for employing surgical measures. Frequent eating, the drinking of much water, and hygienic living are all important. Many clinicians institute a rigorous dietetic régime in gallbladder lesions. Thus, all fats are prohibited, likewise eggs, and other articles of diet; while as a rule the diet in these cases should not be rich, I am in favor of not forbidding too much. Eggs are generally forbidden because they contain a great deal of cholesterin, but being impressed with the great value of this substance in the cell life, I see no reason for forbidding it. As it is usually carried out by most clinicians, the diet is too weakening for the organism; for in order to fight the disease the body must be kept in good nutritive condition.

The instillation of various medicaments into the duodenum (argyrol, ichthyol, mercurochrome) may be undertaken with advantage; the drinking of Carlsbad water, or the like, at home or at the spring seems to be beneficial; glycerine in teaspoonful doses before meals is often useful; salol and urotropin are also frequently given with advantage. Lyon employs magnesium sulphate instillations into the duodenum, and then drainage of the contents.

The indications for surgery may be put as follows:

1. Severe attacks of biliary colic appearing frequently and interfering with the patient's well being —especially if accompanied by a slight rise in temperature.
2. Biliary colic accompanied by fever and a high leucocytosis with an increased polynuclear count, and jaundice.
3. Pains in the gallbladder region accompanied by chills and a high leucocytosis.
4. The indirect reflex symptoms mentioned, such as angina pectoris and cardiospasm, existing for a considerable length of time and reducing the patient's strength.
5. Gallbladder lesions with probable malignancy.

When an operation is performed in these gallbladder conditions, the surgeon is likely to find associated lesions in the abdominal cavity which require attention. Here I would like to say that the operation should not be too extensive, and if conditions are found which are the result of nature's reparative processes they should be let alone if possible. I know of two cases of duodenal ulcer with gallbladder lesions in which by natural processes a stone had left the gallbladder, the gallbladder having become adherent to the duodenum and perforating it so that the gallbladder was in direct communication with the duodenum. The surgeon after performing a gastroenterostomy, tried also to do some plastic work on the duodenum after excising the gallbladder, with bad consequences.

Duodenal Motility*

By HOMER WHEELON, M.S., M.D.,
Seattle, Washington.

The purpose of this paper is to offer certain experimental findings which, I hope, will tend to a more thorough understanding of the motor phenomena of the duodenum. The amount of information pertaining to the stomach and intestines as a whole is such that a comprehensive understanding of their normal functionings makes possible a rational interpretation of functional deviations. Quite the contrary is found relative to the duodenum specifically. The general state of knowledge concerning the motility of the duodenum is well illustrated by Carmen (1) who states:

"Peristaltic movements in the duodenum are difficult to detect. Under ordinary circumstances the bulb is seen to fill, then suddenly to overflow into the descending and transverse portions, through which the barium races quickly, and the entire duodenum is more or less completely evacuated, seemingly as though by syphonage, rather than by an active, expulsive contraction of the duodenum itself. However, competent observers, including

---

*From the Polyclinic, Seattle, Washington. Read in part before the King County Medical Society, Seattle, Washington, November 6, 1922.

Holzknecht, have noted actual peristalsis, rhythmical in character, at minute long intervals."

Again, to quote Alvarez (2a):

"The duodenal cap tends to remain filled during the early stages of digestion. This may be due to the low rhythmicity of the muscle in that region, to its thinness and weakness (in man), to its firm attachment to the mucous membrane and perhaps to the peculiar festoonlike arrangement of the fibres. Particularly towards the close of gastric digestion there is normally regurgitation of duodenal contents into the stomach. Once past the cap the food runs rapidly through the rest of the duodenum and jejunum."

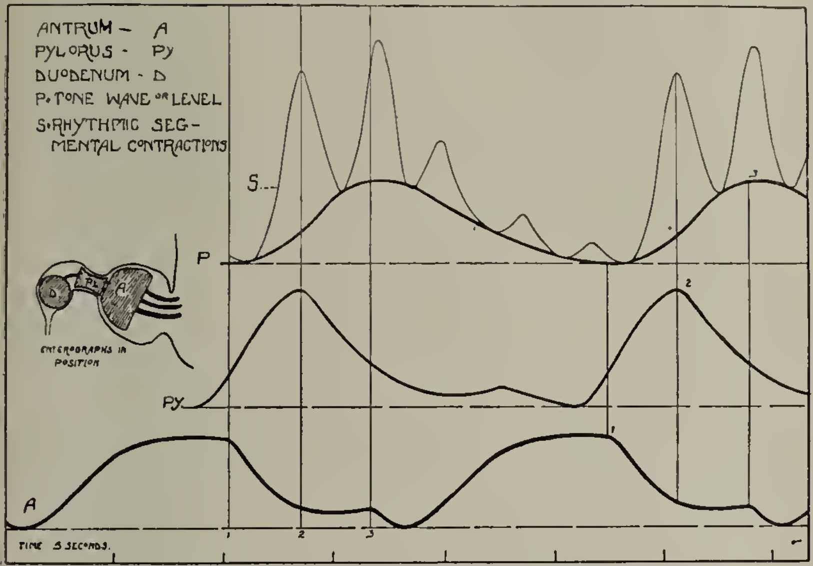

Fig. 1.—Diagram showing the average relation of motor activities in the duodenum, pylorus and antrum of the dog. Data for the compilation of this diagram was obtained by the use of enterographs placed in the lumen of the three parts. The diagram is so arranged that a complete cycle of motility is represented as beginning in the antrum and ending in the duodenum. 1, 2, 3, lines drawn to show synchronous points on the three curves. The insert represents the portions occupied by the enterographs. Note that the maximal contraction in the three parts appear in sequence also that the duodenum is at its greatest degree of relaxation after the antrum has ceased contracting and during the period of rapid contraction of the pylorus. The maximal height of contraction, P. wave, in the duodenum occurs while the antrum is relaxing prior to a succeeding wave of contraction.

At the present time two types of movement are recognizable in the small bowel; first, rhythmic segmental contractions and, second, peristalsis.

"Rhythmic segmentation" of the small bowel, first studied radiographically by Cannon (3a) and graphically by Bayliss and Starling (4), is characterized by movements which divide and redivide the food mass but which do not carry the intestinal content downward. Radiographically observed (animals and man) such contractions appear from five to ten centimetres apart, divide the food column into sections and then give way to similar contractions arising midway between points of previous contractions.

The forward movement of food in the small bowel, as in the stomach, accompanies peristaltic waves or socalled peristaltic rushes (2). Such waves, as shown by Bayliss and Starling (4), are characterized by contraction of the gut musculature above the food mass and relaxation below—law of the intestine.

From the foregoing statements relative to the small bowel it might be inferred that motor activity of the duodenum is of the same nature; however, the paucity of exact information on this point is a challenge to any such deduction.

The following discussion, to a large extent, is based upon the results of animal experimentation.[1] It is true that observations made on one type of animals are not entirely applicable to other types. However, it has been by animal experimentation that many of the principles of human physiology have been established.

The most constant type of motility, graphically observed, in the descending portion of the duodenum is that of rhythmic segmentation. The contractions, occurring at an average rate of fifteen a minute, may be observed during gastric activity or inactivity, also during tone changes in the duodenum itself. Small amounts of morphine or pilocarpine seem to enhance this type of motility.

During active gastric motility, rhythmic contractions of the duodenum show marked alterations in the height of the individual contractions and the tone level from which they are initiated. However, these alterations recur periodically and in such a manner that a line drawn to connect the points of greatest relaxation—tone level—forms a twophased wave. These twophased waves, in turn, are rhythmically repeated; that is, they depend upon the periodical grouping of the segmental contractions.

This type of motility may be observed in anesthetized and unanesthetized dogs for long periods of time, especially if the stomach is active. Further, this periodicity in the grouping of segmental contractions bears a definite relation to gastric motility. This point I wish to discuss more fully for through its interpretation we derive the conclusion that the periodical alterations in the extent of segmental contractions is representative of the passage of true peristaltic waves. For brevity's sake, I will quote

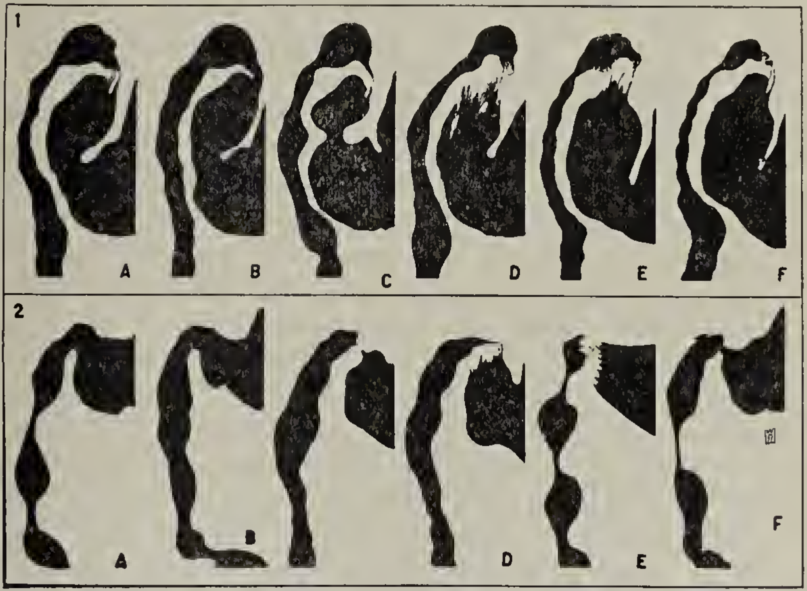

Fig. 2.—Copies of radiograms (dog) showing the sequence of motor activities in the antrum, pylorus and first portion of the duodenum. The exposures for each series (1 and 2) were made approximately fifteen seconds apart, hence they do not show a true series of events for a specific gastric motor cycle. However, the positions shown were repeatedly obtained on the same animal and comply so fully with results obtained by graphic means that they may be taken as representative of the various position of barium during the passage of a peristaltic wave over the stomach and duodenum. As will be noted, an active antrum is associated with a patent pylorus and filling duodenum. The pylorus is seen forcibly contracting at the close of the antral positive phase and while tone is mounting in the duodenum. During this time the antrum rapidly relaxes. During the period of relaxation of the antrum and pylorus the duodenum shows marked activity. At F is shown the condition just previous to the appearance of a second positive wave in the antrum.

---

[1] The writer is keenly aware of the limitations incident to acute experiments. It is true that information so gained is not to be considered as entirely indicative of normal activities. However, when dissimilar methods yield similar results it seems reasonable to believe that such results are indicative of functions normal to the organ studied (5).

concerning this point from a previous paper. (5-b) "Direct, graphic and radiographic observations show that the antrum and pyloric sphincter are rhythmical in action, that is, contractions and relaxations follow each other in a regular sequence. These rhythmical actions or cycles occur at the rate of from three to five a minute, and are maintained for hours."

"The sequence of action in the pars pylorica is as follows: During the active phase of the preantrum there occurs a loss of tone or inhibition in the antrum as a whole. This is immediately followed by a gradual or running contraction of the antrum, the entire antrum demonstrating a sustained contraction or plateau as the final act of its positive phase. This is followed by a wave of relaxation, which, starting in the preantral region, passes over the entire antrum. The sphincter, on the other hand, demonstrates a negative phase (relaxation) at the time of beginning antral contraction. Sometime before the antrum enters upon its held contraction the sphincter begins to contract rapidly and reaches its maximum, usually at a time of marked relaxation of the antrum. The sphincter then relaxes and remains quiet until a second positive phase is well initiated in the antrum. Hence, the sphincter is open during the greater part of the antral contraction and actively closed while the antrum is relaxing" (Fig. 1). In other words, the pyloric sphincter acts as any segment of gut to the passage of a peristaltic wave.

Segmental contractions of the duodenum are greatest during the period of beginning antral relaxation. They are smallest at the height of antral contraction. The level from which the individual segmental contractions occur is greatest after the onset of antral relaxation and least immediately following completion of antral contraction and while the pyloric sphincter is rapidly contracting. The tallest segmental contraction in the periodically repeated grouping of contractions arises from the point of greatest tone depression and rapidly mounts to complete its positive phase synchronous with that of the sphincter. (Fig 1.) The second and usually the third segmental contractions of the group arise from higher tone levels, while remaining contractions arise from progressively lower levels. Hence, as stated above, a line drawn to connect the points of greatest relaxation in any group of segmental contraction forms a wave (line P in Fig. 1), which has a definite relation in sequence of appearance to those formed by the antrum and sphincter, that is, the duodenal wave begins its positive phase sometime after the antrum has ceased to contract and while the sphincter is rapidly contracting. The greatest height of the duodenal wave occurs at a time when the antrum is "inhibited" preparatory to a contraction and while the sphincter is rapidly relaxating. The inactive phase then continues throughout antral and the greater part of sphincteric contractions. Inasmuch as the motility of the three parts is rhythmically repeated, it may be concluded that the wave shown in the duodenum is the result of the passage of a progressive wave into it from the stomach.

If this conclusion is accepted, then an easy explanation may be offered for the peculiar grouping of segmental contractions of the duodenum. If the socalled law of the intestine, as applied to peristalsis in the stomach and small bowel, is applied to the antrum, pyloric sphincter and first part of the duodenum, then it becomes apparent that a positive phase, for instance in the antrum, would be associated with inhibition of the sphincter and structures below. The passage of the positive phase into the sphincter would be associated with relaxation of the antrum and duodenum. Once the positive phase had passed into the duodenum, the antrum and sphincter should show relaxation. This, as already mentioned is the observed phenomena as graphically (Fig. 1) and radiographically (Fig. 2) obtained.

Segmental contractions of the duodenum may, and often do, occur independent of any other type of motility. At such times, however, the individual contractions occur from a constant level and are of the same height. As already mentioned, segmental contractions of the duodenum, during active gastric motility, tend to group themselves in series of rhythmically appearing differences in height and level from which they occur, the rate remaining constant. Hence, if diphasic waves of motility are passed over the duodenum then segmental contractions should be enhanced during the passage of the positive phase and increased tone and depressed during the passage of the relaxation phase and decreased tone. That is, the height of contractions and the tone level from which they occur should be greatly influenced by the running of a peristaltic wave over the duodenum.

At the present time there seems to be a rather ill defined belief that gastric and duodenal motor activities are separate and distinct processes. However, when it is remembered that the duodenum is called upon to receive material from the stomach it becomes evident that the two portions must work harmoniously for the general economy.

I am of the belief that a more thorough understanding of the physiology of the pyloric sphincter would have led to a better understanding of the motor activities of the duodenum. The previous teaching of an "acid control of the pylorus" (3-b) left one to infer that the duodenum was forced to receive material from the stomach at such times as the acid concentration of the gastric chyme was sufficient to effect an opening of the sphincter. More recent studies, especially those of Cole (6), Luckhardt, Phillips and Carlson (7) and Wheelon and Thomas (5-c) have pointed to the conclusion that the sphincter acts in principle as any other portion of the gastrointestinal tract, the differences in detailed action depending upon differences in the mass and gradients (Alvarez 2) of contractile units.

The striking difference between the motility of the stomach and the duodenum is the apparent absence of segmental contractions in the stomach.[2] Here then is a condition in the duodenum which must be brought into correlation with peristalsis.

---

[2] Alvarez (2-b), has recently shown that there are "a number of different types of gastric peristalsis" and that "the stomach can change suddenly from one to another. At times, there seems to be a dissociation between the activities of the fundus and the pars pylorica. The fundus can contract several times to the antrum's once. Small, frequent waves are sometimes superimposed upon the larger, slower ones."

As shown above, the first segmental contraction of the duodenum when occurring in a series of repeated variations, arises from a low tone level and rapidly contracts to reach its maximum synchronously with the closure of the pyloric sphincter. The second contraction, although arising from a higher tone level, is completed after the stomach has begun to relax and while the peristaltic wave in the duodenum is announced by the increased activity of the segmental contractions. The first segmental contraction in the duodenum following the arrival of the peristaltic wave is completed synchronously with that of the sphincter some three seconds following beginning relaxation of the antrum. Hence, the first segmental contraction entering upon its positive phase acts to carry on the function of the pyloric sphincter in that its positive phase is completed along with that of the sphincter, and while the peristaltic wave is gaining strength in the duodenum. Once the positive phase of the peristaltic wave is established the sphincter need no longer remain closed for the reason that the gastric (antral) portion is in a state of relaxation preparatory to the passage of a succeeding peristaltic wave.

These presentations and conclusions find certain corroboration in the studies of Alvarez (2). According to this observer "peristaltic rushes may seem to arise in any part of the small bowel and may run either short or long distances. Many graphic records show, however, that even the short rushes, which, so far as the eye can see, have arisen in the lower ileum, are generally based upon ripples which have come from the duodenum. As some of these ripples can be shown to have left the first portion of the duodenum just after a gastric wave reached the pylorus, it may easily be thought that they had their origin as high as the stomach."

According to my findings the supposition offered by Alvarez is substantiated, that is, peristaltic waves in the duodenum have their origin in the stomach.

Since the publication of my experimental work (5-c) and the prophesy stated above, Alvarez (2-b), working with his newly devised electrogastrograph, was able to verify his own prediction. In speaking of his results he states:

"Another interesting point brought out with the new method is that the stoppage of the gastric waves at the pylorus is not so complete as has hitherto been thought. We can see now that the approach of a wave in the pars pylorica is the signal for the appearance of a strong tonus wave in the first portion of the duodenum. The new records show, moreover, that the rush waves down the bowel always originate in a gastric contraction, which, as we have seen, raises the tone of the duodenum."

CONCLUSIONS.

1. The duodenum of the experimental animal executes two types of motility; first, segmental contraction; second, peristaltic waves.

2. Peristaltic waves in the duodenum bear a definite relation to the sequences of motor activity in the antrum and pyloric sphincter.

3. Hence, peristaltic waves in the duodenum may be considered as having their origin in the stomach.

Some Observations on Duodenal Alimentation*

By JULIUS FRIEDENWALD, M.D.,
Baltimore, Md.,
Professor of Gastroenterology, University of Maryland
and
PAUL FOREMAN WIEST, M.D.,
Baltimore, Md.,
Assistant in Gastroenterology, University of Maryland.

Since Einhorn (1) first described his method of duodenal alimentation this procedure has been utilized to great advantage in the treatment of a variety of affections of the gastrointestinal tract. The various publications of Einhorn, as well as those of many other clinicians, attest to the accuracy of this statement. Notwithstanding the simplicity of its application, as well as its advantages in many affections well recognized by the specialist, it has not as yet received that general acceptance from the practitioner that its value merits. It is on this account that we are desirous of again directing attention to this method of treatment, by no means new, but which to us in many instances has been without question a life saving measure.

The duodenal tube is ordinarily swallowed in the morning with the stomach in the fasting state. Formerly it was thought that in order to have the tube enter into the duodenum it was necessary to pass it at night when it usually found its way into the duodenum on the following morning. It is unnecessary, however, under ordinary conditions to pursue this long procedure. As a rule if the tube is swallowed in the morning on the fasting stomach it will enter the duodenum in from twenty to forty minutes.

In order to accomplish this with greater facility, the method advised by Lyon should be followed. The tube is swallowed to the 55 cm. mark. A small glass of water is taken to increase peristalsis and the patient, then lying on his right side, is required to make slow swallowing movements which gradually induce the passage of the tube to the 75 cm. mark. As Lyon points out, and our observations are entirely in accord with his, the slow swallowing movement is often the secret of the rapid entrance of the tube into the duodenum.

---

*From the Gastroenterological Clinic of the Department of Medicine, University of Maryland.

In order to determine whether the tube has entered the duodenum, it is necessary only to aspirate with the ordinary glass syringe, when usually a light golden yellowish fluid appears. At times, the contents may be slightly amber in color and turbid or a yellow brown. The secretion is usually alkaline, though at times it is neutral or even acid in reaction. Another simple method to determine the location of the tube used by us is to inject a barrel of air from the syringe through the tube. If the tube has not passed the pyloric sphincter a loud gurgle is heard. Should it be in the duodenum a somewhat fainter and more distant gurgle is elicited. After the injection of the air, if an attempt be made to withdraw the plunger one is able to recover the air if the tube is in the stomach, which is impossible should the tube be in the duodenum, due to its smaller calibre and a vacuum which is more readily produced.

While the method mentioned above is not infallible, it affords a fairly accurate working guide. In cases in which there is any doubt as to the localization of the tube, the bulb can be definitely located by means of fluoroscopy.

In those instances in which there is great nausea and vomiting, it is still best, according to our experience, to pass the tube at night while the patient is resting quietly under the influence of a hypodermic injection of codeine or morphine, when it will usually, even in those instances in which the vomiting has been extreme, find its way into the duodenum by the following morning.

As soon as the tube is securely in the duodenum, feeding may be inaugurated at once. Any liquid food may be employed, but mixtures of milk, sugar and raw eggs are the most useful. Care should be taken to see that there are no particles in the food to clog the tube. The amount at the beginning should be small, 100 c.c. every two hours, beginning early in the morning and discontinuing late in the evening.

This quantity may be increased gradually up to 300 c.c. If eight feedings are given in twenty-four hours and each feeding consists of 280 c.c. of milk, one egg, and one tablespoonful of sugar of milk, the patient will receive approximately 2280 calories, which is ample for an average person, and if the patient is at rest in bed it is sufficient to allow a gain in weight.

Einhorn has perfected a special syringe, with which it is possible to administer the food without disconnecting the tube. Morgan has suggested a method like that of Murphy for giving salt solution by rectum, permitting the fluid to flow from an irrigating jar, and so arranging the petcock that the food is taken slowly, the 300 c.c. of nourishment taking about twenty-five minutes. We have at times found this procedure exceedingly useful. The food should be administered at body temperature and the heating should be done slowly, for if it becomes too hot it is likely to become thick and lumpy. After heating, it is well to strain the food to be certain to have it free from small particles. If the food is used too warm or too cold it is apt to cause uncomfortable symptoms, sometimes causing the patient considerable shock; a too rapid administration causing flatulence. After each feeding a syringeful of water at 98°F, should be injected, then the petcock closed and the syringe filled with air, which should be injected after the petcock has been opened; the petcock should then be closed and syringe disconnected. This procedure is important and serves to keep the tube clean and empty. If this procedure is not carried out, small masses of food are likely to be drawn into the lower part of the tube, which may necessitate its removal.

Einhorn advises the following diet list in some instances:

7:30 A.M.	Oatmeal gruel ..	180 c.c.
	One egg	
	Butter	15 gm
	Lactose	15 gm
9:30 A.M.	Pea soup	180 c.c.
	One egg	
	Butter	15 gm
	Lactose	15 gm
11:30 A.M.	Same as 9:30	
1:30 P.M.	Bouillon	180 c.c.

Lactose	90 gm
Butter	90 gm
Bouillon	360 c.c.

At times when there is a tendency toward diarrhea milk sugar must be omitted and when there is an idiosyncrasy toward milk, this form of food must be withdrawn and broths of various kinds (beef, vegetable) or malted milk may be substituted. When milk is well borne its caloric value can often be greatly increased by the addition of varying quantities of cream. It is interesting to note that patients fed by means of the duodenal method usually retain their weight and strength during the entire course of treatment.

The tube rarely causes disagreeable symptoms in the form of nausea or discomfort in the abdomen, if the precautions already noted are carefully followed; it may be retained as long as ten to fourteen days at a time, after which it should be removed, cleaned and if necessary again introduced.

We have never observed in our experience any untoward effects as the result of the metallic bulb or any ulceration or erosion produced by allowing the tube to remain in place over a long period of time. We have, therefore, not found it necessary to sew the bulb to the end of the rubber tube with catgut according to the Buckstein (2) method with the object of allowing the bulb to escape after the catgut has been absorbed.

Attention should be directed to the importance of insisting on frequent rinsing of the mouth with some antiseptic wash, as well as the chewing of gum to prevent oral infection while the tube is *in situ*.

INDICATIONS FOR DUODENAL ALIMENTATION.

While the indications for duodenal feeding are varied, Einhorn first called attention to its main applications in the treatment of gastric and duodenal ulcerations.

More recently (3) he has again advised its use in these affections. Of 315 cases reported by him the immediate results of treatment were satisfactory in all excepting four.

We have utilized this method of treatment for years in certain instances of ulcer, that is, the severe forms associated with intense nausea, vomiting, recurrent hemorrhage, moderate retention and especially in those cases which have not been relieved by the usual methods of treatment. It has been unusually successful in many instances and we are confident that it has been a lifesaving measure in a number of cases. Of special interest too, are those cases to which Einhorn (4) has called attention a few years ago: ulcers recurring after operations. These cases are not infrequent, and we believe, that before a second operation is contemplated, unless there should be pyloric obstruction or some other surgical complication, this method of treatment should be undertaken and in many instances, cure will be effected.

During the period of duodenal alimentation for ulceration, the patient should be required to remain in bed for the first week or ten days and during the remainder of the time should be allowed to be up for a part of the day. The feeding is usually kept up for about two weeks, but if necessary, it may be continued for a longer period of time. After the tube is withdrawn, nourishment is given by mouth for a short time in the form of liquids at two hour intervals to be followed finally with semisolids and solid food.

While the duodenal feeding is being maintained, the usual alkaline treatment may be continued by mouth. By means of duodenal feeding in cases of ulceration, the stomach is spared all irritation while healing ensues and at the same time, the required degree of nutrition is maintained. It is remarkable how quickly nausea, vomiting, pain and even hemorrhage subside under this character of treatment, but notwithstanding the immediate relief obtained, the duodenal alimentation should be continued at least for the entire stated period of from twelve to fourteen days.

While duodenal alimentation is extremely valuable in the treatment of some forms of ulceration of the stomach and duodenum, there are other conditions in which its use is equally beneficial. Of these, we wish especially to call attention to a rather large group of cases of a high degree of atony of the stomach, frequently associated with a maximum form of enteroptosis in which on account of the patient's inability to take food or at least an adequate quantity, malnutrition with great loss of flesh is produced. Einhorn (5) and C. R. Jones (6) have called attention especially to the beneficial effect resulting from duodenal alimentation in this group of cases.

In many instances of this affection, there is an associated marked anorexia and the patient may present an alarming appearance, not infrequently simulating carcinoma. According to our experience, duodenal alimentation brings about most beneficial results in this class of cases, with gain in flesh, strength and general nutrition, but must often be continued for over a period of at least three or four weeks. In most instances, after withdrawal of the tube, forced feeding may be inaugurated with further success.

Duodenal alimentation is of great value in the treatment of nervous anorexia and sitophobia. Both of these conditions due either from lack of appetite or fear of food, which may have extended over a considerable period of time, are followed frequently by much loss in weight as well as in strength. In not a few instances, due to an associated mental depression, the insistence and encouragement on the part of the physician to have the patient take food prove useless. In our experience in a number of patients affected with these disorders, the adipose tissues had almost completely vanished and even many of the muscles had been so largely atrophied that voluntary movements had become difficult and at times impossible. When a case has advanced to this stage, the danger of a fatal outcome is imminent.

Carnot and Libert (7) have recently reported a case of this character relieved by duodenal feeding. In many of these cases, duodenal alimentation is the only means by which a cure can be effected and often the associated mental disturbance is overcome due to a gain in weight and strength.

Another indication for the need of duodenal alimentation is when vomiting, which may be due to a variety of causes, occurs. Of these, nervous vomiting is the most frequent. Paddock (8) has recently advised this form of treatment in hyperemesis gravidarum. We have advised this procedure in several instances with favorable results. In all aggravated forms of nervous vomiting, it is wise to follow the plan noted above; that is, to introduce the tube at night after the patient has been placed under the influence of codeine or morphine, and in most instances, the tube will be found *in situ* on the following morning.

Finally, duodenal alimentation has proved exceedingly useful in the relief of nausea, vomiting and discomfort following certain surgical procedures. In persistent vomiting following anesthesia, which has extended over a period of a few days, it may be the only means of giving nourishment and preventing extreme exhaustion and weakness. After gastroenterostomies or other surgical procedures on the stomach, when persistent vomiting and discomfort have occurred sometime following operation, we agree with Einhorn (4) that there is no more efficient method of treatment, in many instances, than by means of duodenal alimentation.

A brief review of the following cases will illustrate the value of duodenal feeding:

Case. 1.—Persistent nausea and vomiting associated with gastric ulcer, extreme weakness, exhaustion and loss of flesh. Recovery under duodenal feeding. T. J., male, aged thirty-four years, had been affected with indigestion for the past ten years with periods of remission extending over three or four weeks at a time during which he was unable to take any form of food without discomfort. During the periods of indigestion, the patient complained of pains in the region of the stomach, occurring two hours after meals, which were, up to recently relieved, by the ingestion of food and alkalies; of acidity, nausea and occasionally vomiting. During the past three weeks, the symptoms had become greatly aggravated—pain, nausea and vomiting being persistent. The patient lost twenty-five pounds in weight, had become weak and easily exhausted. Physical examination revealed a much emaciated individual with heart and lungs normal; a tender area was elicited in the epigastrium. Gastric analysis revealed free hydrochloric acid 45, total acidity 68 (Ewald test meal). A röntgen ray examination revealed an ulcer at the pylorus with evidences of marked pylorospasm.

The usual Sippy ulcer management was instituted without avail, the patient vomiting nourishment as well as alkalies immediately. After three days' trial it was abandoned. The patient was then allowed to swallow the duodenal tube at night while resting and under the influence of codeine, and feeding instituted the following morning, after which no further discomfort was noted. He began to gain weight and strength within a week's time and after the removal of the tube in two weeks was able to take nourishment and complete his ulcer cure. After two years, the patient continues to remain perfectly well; a recent x ray examination revealed a perfectly normal condition of the stomach and duodenum.

Case II.—Marked atony and visceroptosis, indigestion, emaciation, weakness, inability to consume sufficient nourishment, no relief following rest cure. Complete relief by means of duodenal alimentation followed by rest cure. B. S., female, aged twenty-eight years, complained of indigestion for a period of four years, consisting of pressure, fullness, distention, constipation, and on account of distress produced by food was unable to take sufficient nourishment. The patient had gradually lost twenty pounds, weighing but seventy-eight pounds, and was extremely weak. Physical examination revealed an extremely emaciated individual presenting definite signs of a visceroptosis with marked gastrointestinal atony. An x ray examination confirmed the physical findings. A thorough rest cure had previously been given without avail. By means of duodenal feeding extending over a period of three weeks, the general nutrition was improved and the gastrointestinal symptoms disappeared. The patient was now placed under a complete rest cure with forced feedings and was discharged as well in nine weeks, having gained thirty-three pounds in weight.

Case III.—Nervous anorexia and vomiting, sitophobia, marked loss of weight and strength, mental depression. Complete recovery under duodenal feedings. K. O., female, aged forty-nine years, had been complaining of nervousness, loss of appetite, nausea and vomiting more or less for the past two years, following a shock due to a sudden death in her family. These symptoms gradually become intensified and in addition, there was present great fear of food, mental depression and loss of flesh (twenty-five pounds) and unwillingness to take nourishment. On physical examination, no abnormal conditions were revealed.

The gastric analysis and x ray examination of the gastrointestinal tract were essentially negative. No amount of persuasion or insistence could convince the patient of the necessity of consuming nourishment. She finally lapsed into a deplorable state of inanition and exhaustion. The patient was put to bed and after some difficulty the tube was introduced and feeding instituted, which was continued for a period of three weeks. The patient gradually improved in weight and strength and after removing the tube began to take nourishment normally and in the course of two months was apparently well both physically and mentally.

Case IV.—Gastric ulcer extending over a period of five years; gastroenterostomy; relief for six months; cured by means of duodenal feedings. S. M., male, aged fifty-four years, had been having symptoms of gastric ulceration, extending over a period of five years for which gastroenterostomy was performed. At operation a rather large ulcer was located near the pylorus, not producing any obstruction. The patient had complete relief for six months, when pain occurring several hours after food, symptoms of hyperacidity and nausea began to manifest themselves. An x ray examination revealed a large ulcer on the lesser curvature near the pylorus; there was no obstruction; the gastroenterostomy opening was apparently no longer functioning. A Sippy cure was undertaken without relief, the symptoms becoming aggravated. Operative intervention was advised but was refused by the patient.

Duodenal feeding was then undertaken and carried on for a period of two and one half weeks. The patient was promptly relieved and after removal of the tube has not been troubled from further distress. Careful feeding was continued for a few weeks longer, when the patient was discharged apparently well. An x ray examination made again of the stomach three months following the cure, revealed perfectly normal conditions.

CONCLUSION.

1. In duodenal alimentation a method of feeding has been established, which is not as a rule exceedingly uncomfortable to the patient when the technic is properly carried out, and which enables us to maintain nutrition when food cannot be taken in sufficient amounts in the normal way.

2. It is especially useful in the treatment of gastric and duodenal ulcer of a severe type associated with intense vomiting, nausea and recurrent hemorrhage and especially those forms which have resisted the usual methods of treatment. By means of this method of feeding, the stomach is spared all irritation while healing occurs and at the same time the requisite degree of nutrition is maintained.

3. Duodenal feeding is of great value in the treatment of cases of atony associated with a maximum degree of prolapse of the stomach and intestine, in which on account of the anorexia, the patient is unable to take an adequate amount of food and in which malnutrition with great loss of flesh is produced. This form of feeding is extremely helpful at times in overcoming nervous anorexia and sitophobia, which are often associated with much loss of flesh, strength and mental depression.

4. It is useful in relieving the vomiting, which

may be due to a variety of causes; i. e., nervous vomiting and the vomiting of pregnancy.

5. It is a valuable means of cure at times following surgical procedures on the stomach, when nausea, vomiting and discomfort have recurred sometime following operation.

6. Finally, in duodenal alimentation Einhorn has given us a most valuable method of feeding which in many instances has proved a life saving procedure and which must be classed as one of the most useful therapeutic measures developed in recent years.

Etiology of Gastroduodenal Ulcer

Why the Stomach Does Not Normally Digest Itself

By E. PALIER, M.D.,
New York.

In 1921 I published a preliminary communication on the subject of gastric ulcer. In this article I propose to deal with the matter in greater detail, the more so as my previous communication has apparently not been noticed in this country, either from lack of appreciation, or from sheer neglect and indifference. Many theories have been advanced in explanation of the subject in question, but unfortunately upon strict analysis they do not agree with well known and well established facts.

Many experimenters state that they have produced gastric ulcers experimentally in the lower animals, in one way or another, but their conclusions are at variance with what is known concerning the physiology and the pathology of the human alimentary canal and the occurrence of this affection in man. I would advise those who are interested in the subject of gastric ulcer to read over Welch's monograph (2) on this subject. Although written over a quarter of a century ago, it contains a wealth of information, interesting at least from a negative side.

The theory concerning gastric ulcer which has recently gained ground in this country and in England is the microbic theory. Now I am not a Christian Scientist or a chiropractor, two of the most dangerous cults of ignorant and swindling quackery that infest this country, and I am fully aware of the rôle played by microorganisms in the causation of diseases. But to incriminate microorganisms as an etiological factor in a disease when this factor does not exist is as reprehensible as its denial when it does exist.

Now to criticize the work of men who have a high standing in the profession, particularly when they occupy high positions in well endowed institutions, is a very ungrateful and at the same time disagreeable task. But it has to be done as a matter of veracity, not personality, before I expound my theory on the subject.

The microbic theory of the affection in question was advanced by Böttcher (3) as far back as 1874. In this country Turck (4) and Rosenow (5) have been its most ardent exponents and lay claim to having produced gastric ulcers experimentally by bacteria. Turck incriminates the colon bacillus, whereas Rosenow considers the streptococci as an etiological factor and according to him they make their entrance through the venous circulation.

A British pathologist asserts that he has found streptococci in the stomachs of cadavers with gastric ulcer, and he infers therefrom that the streptococci are the cause of the ulcers. This, of course, is too absurd to be discussed, as the stomach of a cadaver and that of a living being are entirely different.

Now, I have no reason and no right to doubt the veracity of Turck, Rosenow and other experimenters who state they have produced gastric ulcers by microorganisms or in any other way; but in answer to this I will quote again the following from Welch (6): "The most interesting of those experiments are those of Cohnheim and Dactwyler, who demonstrated that in one essential point all of these experimental ulcers differ from simple gastric ulcer in man—namely, in the readiness with which they heal. To this ready healing the gastric juice . . . seems to have offered no obstacle. . . .

"It appears from these experiments as well as from observation on man that it is more difficult to understand why ulcers of the stomach do not heal than it is to understand how they are produced."

Welch is perfectly right, as ulcer of the stomach is not a mere local infection, but it is a constitutional disturbance with local manifestations.

Now as for the microbic theory of gastric ulcer there can be no doubt in the minds of those who have had experience in gastrointestinal diseases that in the vast majority of cases there is either hyperchlorhydria or normal acidity in connection with this affection. Gastric ulcer with hypochlorhydria or total achlorhydria is the exception and not the rule. This latter condition occurs usually in old cases where a gastritis anacida has supervened to the ulcer. The fact is that we can seldom state with certainty the exact date of the onset of the ulcer.

Now in a number of works which I have published in English (7), French (8), and German (9) I have shown that in hyperchlorhydria and in normal acidity the only bacteria which are found in the stomach contents after a test meal or another light meal are yeast, fungi and a small bacterium which I named

Bacillus chlorhydrici (10). Under certain conditions one can find other microbes, but they are not constant. In subacidity or anacidity of the stomach any microbes can be found. The same holds good for gastric ulcer, which, as I have said before, is usually associated with hyperchlorhydria or normal acidity. But in order to determine this, it is not enough to examine a drop of gastric juice on a slide under a microscope, as is usually done by clinicians, but cultures and animal injections must be made. Furthermore, precautions must be taken in obtaining the gastric juice so as to prevent its contamination with the bacteria from the throat and mouth (11).

Turck asserts in one of his articles that the acidity of the stomach contents favors the growth and development of the colon bacilli. I regret to state that such a statement is utterly at variance with the facts of elementary bacteriology. It is true that a slight organic acidity does not hinder the growth of these microbes, but the degree of inorganic acidity of the stomach in normal acidity and especially in hyperchlorhydria is certainly not favorable for the growth of bacteria, except yeast and certain fungi which thrive best in an acid medium, particularly hydrochloric acid. In the laboratories, as is well known, the culture media for bacteria, including the colon bacilli group, are neutralized when they are prepared.

But I know that it is a difficult task to convince the reader who has not made bacteriological examinations of the gastric contents or who is not well versed in bacteriology in general, and I regret to have to say that very few indeed have a sound knowledge of bacteriology, though numerous are those who dabble in it and imagine they know it—of the correctness of my view in the laboratory domain. It is a question between my statement and the statement of others and the reader may be inclined to accept the view of others.

I will therefore leave the laboratory domain and take up some well known, well established, undoubted, pathological and clinical data concerning gastroduodenal ulcers, which cannot be questioned by anyone, except by a Christian Scientist or a chiropractor. These facts will speak for themselves and there can be no more question as to whose statement deserves more credence.

These are the facts:

1. The age of patients affected with gastric ulcer. This is a disease of adult life. There is no division of opinion on this point. A gastric or duodenal ulcer in infancy is considered a rarity, and some authors even doubt whether it ever occurs and consider the few reported cases not as true ulcers but as erosions (12). It would be superfluous for me to occupy space by quoting authorities in support of this view. Now if gastroduodenal ulcer were due to an infection by the colon bacilli or by cocci, why would children be so singularly exempt from the disease in question? We know as a fact that children are subject, in fact more so than adults, to infection by these microorganisms.

2. Systemic disturbances, such as fever, acceleration of pulse and other symptoms, are absent in gastric ulcer, except in certain complications. "It is an afebrile disease," as Welch expresses it. Now if it were due to a bacterial infection, to streptococci entering through the circulation, as stated by Rosenow, or to an infection by the colon bacilli, there would certainly be some systemic disturbances as a rule.

3. The pathological anatomy of gastric and duodenal ulcers. There are two types of ulcers—the round ulcer and the craterlike ulcer. I avoid the terms acute and chronic ulcer as being simply a vague, arbitrary, clinical definition. Now the round ulcer has sharply punched out borders, and a smooth bottom.[1] The craterlike ulcer defines itself—it is in the form of a crater, is indurated, sclerosed, and frequently it involves quite an extensive area, and it is often transformed into a carcinoma. These are facts again about which there is no divergence of opinion among pathologists.

Are these the characteristics of an infectious ulcer caused by colon bacilli, streptococci or other known bacteria? Certainly not. The latter is characterized by sinuous, granular, undermined borders, uneven spongy bottom, bathed in pus. Verily, I must say it is incomprehensible that the difference cannot be plainly discerned by all.

From these undisputed and indisputable clinical and pathological facts it ought to be seen that the microbic theory of gastric or duodenal ulcer is untenable. A theory that does not agree with well established facts must, of course, be rejected. We cannot build a theory on the experimental production of a phenomenon, if it is in disaccord with what we know of the same phenomenon when it spontaneously occurs in Nature. It is like stage thunder compared with real thunder.

What, then, is the cause of gastric and duodenal ulcers? The local cause is chemicomechanical, the underlying one is constitutional—namely, a disturbance of metabolism, and it can be defined as a constitutional disease with local manifestations.

In examining the urine in gastric troubles as a matter of routine, I have found that in cases of ulcer the urine contained an excess of alkaline earthy salts, and its reaction was less acid than normal, in some cases neutral or even slightly alkaline. Thus the reaction of the urine presented a contrast to the reaction of the gastric contents. These inorganic elements consist either of phosphates or carbonates or both. They are precipitated by heat and are redissolved by the addition of inorganic acids, in some cases with a rapid, energetic effervescence, and in other cases without effervescence or with a very slight one on the addition of acetic acid or the inorganic acids.

I also found an excess of those inorganic salts in the stomach contents in gastric ulcer. Their detection in the stomach contents, however, is not an easy matter and it is best done when some clear gastric juice is obtained on a fasting stomach or a few hours after a light meal. When there are remnants of food in the stomach contents, the matter becomes complicated and delicate. There is thus a general disturbance of metabolism, particularly of the inorganic salts, with an excess of it appearing in the stomach contents and in the urine.

Before I proceed, however, to expound the pathogenesis of the formation of gastroduodenal ulcers, I will briefly state the reason why the stomach and for that matter the intestines do not normally digest themselves, a question that has baffled physiologists from time immemorial. The explanation that the alkalinity of the blood neutralizes the acidity of the gastric juice does not hold good, of course, for the well known objection that it does not explain the reason why the nonacid intestinal contents do not digest the intestines; furthermore, by the fact that the foot of an animal introduced into its own stomach is digested. We know furthermore the unpleasant corrosion of the abdominal skin by the gastric juice following gastrostomy, so that surgeons lately perform this operation in such a way as to prevent this complication (13).

---

[1] The French call it *coupé à l'emporti-pièce*. On the bottom there may be some débris and even bacteria; but they lodged there after the ulcer had been formed.

But the facts are these: As is well known, the stomach as well as the intestines, especially the small ones, are lined with numerous mucous cells covering the entire inner surface. Even mouths of the secreting peptic glands of the stomach are lined with mucous cells. For a long time I could not understand such an extravagance on the part of Nature of putting mucous glands in the digestive tract, since mucus has no digestive power.

At last the light came to my mind. The mucous membrane protects the stomach and intestines against autodigestion, because mucus is not digested or dissolved by the digestive juices of the alimentary canal, and the mucus secreted, as well as the mucous cells, owing to their contents of mucus and their vitality, shield the digestive tract against autodigestion.

If one should ask me why it is that mucus is not digested, I might ask him why the gastric juice does not act on starch and fats, or at least very slightly so, and why oil and water do not mix, and a million or more other questions like this. Since we do not know the riddle of the origin of the world, we shall always come to a question that we cannot answer.

That mucus is not digested or dissolved by the digestive juices can be easily seen in vitro and in vivo in pathological conditions of the alimentary canal. If we withdraw the stomach contents from a patient after a test meal, and this patient is suffering from catarrhal gastritis, the contents containing an abundance of mucus, and we plunge thereinto a strip of congo or Toepfer paper, the reaction may be almost negative, or there may be a change in the color of the paper only in a few spots. One might conclude therefrom that there is hypochlorhydria. If, however, we filter the gastric juice, or better still we let it stand for some time till the mucus separates, falling to the bottom, and we then try the reaction on congo paper, we may obtain a strongly positive reaction, unless it is a real case of subacid or anacid gastritis.

Not wishing to enter here into a discussion of gastritis, I will only say that when there is an abundance of mucus in the gastric contents, several test meal analyses are necessary before the condition can be pronounced as subacid or anacid gastritis. The fact is that the digestive juices of the alimentary canal and acids in general, such as are found in the stomach, do not act on mucus. The intestinal digestive juices, though slightly alkaline, are not, however, sufficiently alkaline to have any effect on the intestinal mucous membrane. Thus the mucous membrane protects the gastrointestinal tract as a shield against autodigestion. Again, an excess of mucus interferes with digestion.

Another factor though less important than the former, but still of great importance, is the peristalsis of the tract during digestion, so that the digestive juices are constantly repulsed from the walls of the canal. The secreting peptic and pancreatic cells do not digest themselves because the secretion is continuously expelled.

This, then, being the reason why the stomach does not normally digest itself, and it is undoubtedly the right reason, we can easily understand the pathogenesis of the gastroduodenal ulcer.[2]

When there is an accumulation or excess of inorganic salts in the mucous membrane of the stomach or the duodenum, first, the vitality of the mucous membrane is thereby impaired, and, secondly, the acid gastric juice acts as an energetic solvent on the inorganic salts and the impaired mucous cells. Once the breach is made, the process may continue till perforation of the gastric wall occurs. In the duodenum the same process takes place, for the ulcer in the duodenum occurs usually in that part of the duodenum where the digestive juice is still acid (14).

Furthermore, the addition of the digestive enzymes to a weak solution of hydrochloric acid, the way the latter is found in the stomach, enhances its solvent power of the inorganic salts. To this conclusion I came from my own researches, but subsequently on looking over Foster (15) I saw in it the following statement concerning the gastric juice: "The minerals that are soluble in free hydrochloric acid are for the most part dissolved, though there is a difference in this and in some respects between gastric juice and free hydrochloric acid diluted with water to the same degree of acidity as the juice, the presence of either pepsin or of other bodies apparently modifying the solvent action of the acid."

The modification consists in enhanced action. We all know that bones, when they are not very hard, are well digested by the human and animal stomach. We have seen how a cat swallows a whole mouse. My theory thus explains the frequent location of ulcer in the pylorus and the duodenum, as well as all other riddles in connection with gastrointestinal ulcers.

This affection, then, is a lithiasis or gravel of the stomach, acted upon by the acid digestive juices, causing the ulcer.

This will explain the hitherto inexplicable phenomena in connection with this disease. Lithiasis or gravel is a rare affection in children, therefore gastroduodenal ulcer is rare among them. Furthermore, the hydrochloric acidity among children is, on the average, much lower than in adults (16). In the aged, gastric ulcer is also rare, unless it dates from an earlier period. A person who up to sixty has not suffered from gravel is not likely to suffer from it afterwards. Besides, the gastric secretion in the aged is, on the average, less active than in younger people. It is second childhood.

Gastric ulcer is an afebrile affection, as Welch says, and as is well known, the same as is gravel of the kidneys, bladder, and other organs, except in certain complications. Its periodicity is also understood. As is well known, there are periods of remission in many cases of chronic ulcers, the acute attacks returning at intervals. The same occurs with gravel in other parts of the body.

---

[2] Recently some authors have ascribed the nondigestibility of the stomach to an antipeptic ferment. But if this ferment were secreted in sufficient quantity it would naturally hinder digestion altogether. And what about the hydrochloric acid and also the yeast of the stomach, and the corroding stomach contents in general.

Furthermore, my theory will also explain the relief in most cases obtained by operations. The patient is almost immediately relieved after a gastrotomy, and the more of the pylorus eliminated the more successful will be the operation (17). If gastroduodenal ulcer were due to a microbic infection it is hard to comprehend how it gets well so soon after the operation. My theory answers this also. The activity of the acid gastric juice on the walls of the stomach, especially the pyloric region, is greatly diminished (18). On the other hand, an ulcer does sometimes occur lower down in the jejunum, after the operation, owing to the action of the acid gastric juice.

To say that the acid gastric juice favors the growth and development of bacteria like streptococci and colon bacilli, is simply baseless and absurd, as I stated above.

My theory will also explain the frequent resistance of the disease to treatment and the frequent relapses after apparent cures, because it is wrongly considered and treated as a mere local affection, with no attention to the deeper underlying cause.

In short, there is not a phenomenon with which I am acquainted in connection with the malady in question that is not explainable by my theory; this in itself entitles it to consideration.

I shall now briefly report a few cases as illustrations:

Case I.—Mr. K., baker, aged thirty, had been suffering from stomach trouble for a long time. There were periods of remission when the patient felt quite well, alternating with severe attacks of gastric pain and other symptoms. The patient came to me with a diagnosis of gastric ulcer ready made, and also brought me an x ray picture, with the diagnosis of gastric ulcer. The patient came for treatment and not for diagnosis. Ewald-Boas test meal: The gastric contents were poorly digested, contained mucus and blood, and showed a hypochlorhydria. The character of the gastric contents made me at first somewhat dubious about the correctness of the diagnosis of ulcer. But after several lavages of the stomach and a milk diet, a second test meal a few days later showed very little mucus and hyperchlorhydria.

This, by the way, proves the necessity of more than one gastric analysis.

Patient's urine: a specimen of the urine is heated in a test tube, and a precipitate occurs. A few drops of concentrated hydrochloric acid are added, strong effervescence takes place, and urine becomes clear. Another specimen of the urine is heated and a weak solution of hydrochloric acid with some pepsin and pancreatin is added; the urine clears up. A weak solution of hydrochloric acid alone dissolves precipitate imperfectly.

Stomach contents: I extract some stomach contents of patient on a fasting stomach. I obtain a few c. c. of clear fluid, very slightly acid. I heat it in a test tube: there is a precipitate formation which clears up on the addition of a solution of hydrochloric acid.

I must repeat here that the examination of the stomach contents for inorganic elements is a delicate matter. If there are food remnants or the acidity is strong, a complicated chemical analysis is required. I will also add that the contents of fasting stomachs of patients where ulcer can be positively excluded do not show any precipitate on heating, or if they do show it, it is not cleared up by the addition of hydrochloric acid.

In dealing with stomach contents it is necessary to use a finer method of analysis than heat and acid. But for the urine this is practically sufficient for clinical purposes. If one has the facilities for finer chemical analysis, so much the better, of course.

In some cases of gastric ulcer, the urine does not continuously show the presence of an excess of inorganic elements.

It disappears for a time and reappears again. Hence several examinations are necessary at intervals, if the result of the first examination is negative.

I will not occupy more space in reporting further cases.[3] I will say, however, that aside from the pathogenesis of gastroduodenal ulcer, I consider the presence or the absence of an excess of inorganic salts in the urine as an important and valuable diagnostic sign in gastric diseases, as valuable as is the presence or absence of tubercle bacilli in the sputum in the diagnosis of tuberculosis. Of course I am fully aware that there is such a thing as phosphaturia without gastric trouble. But in a case which I considered as simple phosphaturia and neurasthenia, and in which the gastric disturbances were very slight, I found, on introducing the stomach tube, a profusely bleeding ulcer. We know that gastric ulcer not infrequently runs a very latent course.

On the other hand, a case which presented some but not full evidence of ulcer, and I diagnosed it as such for a colleague who referred the case to me, and my diagnosis was corroborated by another gastrologist, a man with a large practice, after he had made an x ray examination of the patient, it turned out, at the operation, to be a case of gallstones. The urine in this case, however, was negative. Of course, kidney and bladder disorders must be excluded in these cases.

I sought to corroborate or disprove my findings by the experiences of other physicians who enjoy a vast clinical material. I applied to some, but I obtained no satisfactory answer. I then thought that the best source of information would be the Mayo Clinic at Rochester, Minn., as they have a vast material, and they also have the opportunity to verify the diagnosis by operation. Dr. Mayo kindly referred me to Dr. D. M. Berkman, who has charge of this matter. But he writes to me in answer: "I am very sorry to say that we have made no routine study of inorganic salts in the urine. We shall be interested in your article when it is published. . . ."

So I hope this article will arouse the interest of others and will evoke further research in this connection, and my findings and conclusions may be confirmed. It is very important, not only from an etiological and a diagnostic viewpoint, but from a therapeutic one as well.

151 East Eighty-ninth Street.

Surgical Treatment of Gastric and Duodenal Ulcer*

By JOSEPH J. WELLS, M.D.,
New York.

In recent years there have been marked changes in certain operative procedures, especially as regards the surgery of the upper abdomen. This has been particularly noticeable in the evolution of gallbladder surgery. I need but mention this casually in passing to recall to your minds the controversies that raged when cholecystectomy was first advocated as the procedure of choice in dealing with cholecystitis or cholecystitis with cholelithiasis.

Let us now turn to the subject of this paper, namely, the surgical treatment of gastric and duodenal ulcer. No less radical and striking have been the changes in technical procedure in dealing with ulcer of the stomach.

It is not amiss to review here, briefly, the normal physiology of gastric digestion, and the disturbances that accompany the presence of an ulcer and its progression. The musculature of the gastrointestinal tract, from pharynx to anus, is made up of smooth muscle fibres, and it is a fact, noted in all forms of animal life, that contractions occur from above downward, followed by relaxation in definite orderly fashion. In other words, there is a certain rhythmicity in the movements of the gastrointestinal tract. The movements of the stomach have been studied by different investigators. The first really important contribution to this subject was made by Beaumont in his observations on Alexis St. Martin. In recent years the subject has been carefully studied by means of the x rays. It has been demonstrated by W. B. Cannon that the stomach consists of two physiologically distinct parts. The cardiac portion acts as a reservoir, and it is here that salivary digestion continues. No peristaltic waves are present in this portion of the stomach. In the pyloric portion active gastric digestion goes on. Peristaltic waves apparently are initiated in the middle of the stomach and pass on toward the pylorus. As the food passes from the pyloric portion into the intestines, tonic contraction of the fundus muscles squeezes food into the pyloric portion. As a contraction occurs, the food comes into intimate contact with the secreting surface within the narrowed muscular ring. The food escapes in small amounts on account of the intermittent opening of the pyloric sphincter.

Cannon's chemical theory regarding the opening and closing of the pyloric sphincter, has in recent years been attacked by the experiments of Carlson, Spencer, Meyer, Rehfuss, and Hawk. Carlson's experiments indicate that the pyloric sphincter opens for the ejection of chyme when reached by powerful advancing rings of contractions, and whenever the tonicity of the stomach musculature is greatly increased. Furthermore, Leo L. J. Hardt has shown that the emptying of the stomach is not interfered with in cases of achylia gastrica, since in none of these cases was retention present.

The stomach receives nerve fibres from the vagi and splanchnics, but its orderly movements are merely regulated through these extrinsic nerve fibres. The stomach is essentially an automatic organ, and it has been shown experimentally that gastric movements and gastric digestion may proceed normally after section of these extrinsic nerve fibres. Under normal conditions movements of the stomach are initiated through psychic stimuli, or reflexly through stimulation afforded by the presence of food in the mouth. in the presence of an ulcer we have the direct stimulation of food passing over an inflamed, ulcerated area. This probably gives rise to a reverse peristalsis, thus explaining the symptoms of nausea and vomiting, so regularly present in advanced ulcers of the stomach. In duodenal ulcers we find conditions are somewhat different. Irritation in this area will reflexly cause a spasm of the pyloric sphincter and thus lead to a delayed emptying of the stomach, but no reverse peristalsis occurs, since irritation here is in the duodenum and movements of the stomach remain unaffected. This conception of the mechanism of motor disturbances in gastric and duodenal ulcer would explain the reason for the rarity of vomiting in duodenal ulcer as compared to its frequent occurrence in gastric ulcer. When vomiting does occur in duodenal ulcer, it is probably due to overloading a dilated, atonic stomach.

The problem confronting the gastrointestinal surgeon, in dealing with gastric and duodenal ulcer, is, in the light of our present knowledge, still a difficult one for him to decide. He has the choice of several operative procedures. Shall he do a simple gastroenterostomy and take his chances of eighty-five per cent. cure—the consensus of statistics shows about eighty-five per cent. freedom from symptoms following gastroenterostomy in all types of ulcer of stomach and duodenum. In properly selected cases I believe that simple gastrojejunostomy should still be the operation of choice. In order to be able intelligently to pick the indication for gastroenterostomy, one should be well acquainted with the types of ulcer. For practical purposes, we divide ulcers of the stomach and duodenum into two main types. First, the soft superficial lesion, which does not penetrate further than the submucosa, and which, if followed, shows no tendency to malignant transformation. These are not always distinct types, but may overlap each other. The first type tends to heal, either spontaneously or under medical treatment. The second type, for some unknown reason, fails to heal, and is noted by its chronicity and tendency to progress.

In the first type of lesion, after persistent medical treatment has failed to relieve the symptoms, if repeated hemorrhages occur, or if there is present a marked stenosis of the pylorus, or other portion of the stomach producing hourglass stomach, then operation should be done, and in this type a simple gastroenterostomy, properly performed, will probably lead to a cure in the vast majority of cases. We find that the results of simple gastroenterostomy are especially good in cases of pyloric stenosis, or in cases where the ulcer is situated near the pylorus, without producing marked stenosis.

*Read at the monthly conference of the surgical staff of the New York Post-Graduate Hospital and Medical School Service of Dr. Charles Gordon Heyd, March 21, 1923.

Some operators, notably Davis of Omaha, favor the Finney operation of pyloroplasty. One of its advantages is that the stomach and duodenal walls can be thoroughly explored and the ulcer excised. Finney and Friedenwald report one hundred cases with five deaths. Eighty-two cases followed for one year showed a percentage of 93.6 satisfactory results. The objection to the operation is that it is unsafe to perform in the presence of dense adhesions about the pyloric region, on account of the difficulties of the operation and because of the dangers of postoperative obstruction. It is also inadvisable to do this operation if much thickening of the pylorus exists.

The Horsley operation combines resection of the ulcer with pyloroplasty. It is a much simpler procedure than the Finney operation but many of the objections to the Finney operation exist in the Horsley operation. Eusterman says of pyloroplasty: My experience with the endresults of several hundred well executed pyloroplasties, many performed under favorable circumstances, has not been encouraging. Recurrence of ulcer in the suture line, adhesions to adjacent viscera, induration; contraction and narrowing, which provoke faulty pyloric mechanism and serious functional disturbances in the absence of adequate, obvious cause, are occasional sequelæ. At least fifteen per cent. of all pyloroplasties eventually prepare rich soil for successful gastroenterostomy.

In the second type of ulcer we have an entirely different problem to deal with. It is rather difficult to imagine that a simple gastroenterostomy can lead to a healing of these larger indurated and penetrating ulcers, with their massive adhesions to surrounding organs, especially pancreas and liver. While undoubtedly the mechanical relief afforded by the stoma may lead to amelioration or subsidence of the symptoms, still the relief thus afforded is at best only temporary, and we are almost certain to have a recurrence of the symptoms, with even greater severity than before the operative procedure was undertaken. Furthermore, we are leaving intact a lesion which is fraught with the ever constant danger of malignant transformation, variously estimated at between two and eighteen per cent. C. H. Mayo states that chronic ulcer is the most important factor to be considered in carcinoma of the stomach, as in more than forty per cent. there is a history of ulcer varying from many months to several years before the onset of cancer. We must also keep in mind that on the operating table it is often extremely difficult to differentiate between these hard penetrating lesions and a carcinoma, especially when the ulcer involves the lesser curvature or posterior wall. It seems to me that the only rational treatment in these types of cases is excision of the ulcer bearing area.

Having decided in favor of excision or resection, various methods present themselves.

1. One may excise the local area by means of a V shaped incision, and suture the resulting defect in gastric wall. This procedure should be combined with a gastroenterostomy to relieve certain distressing symptoms which may arise.

Excisions, which are often quite as difficult to perform as resections do not give as good results, especially if the ulcer is situated near the pylorus. Excision should therefore be limited to those ulcers which are situated too far away from the pylorus to lend themselves readily to a resection.

2. If the ulcer is situated near the middle segment of the stomach, we may do a mesogastric or socalled sleeve resection. Woolsey reports nine cases of mesogastric resection. There was no mortality in his group and while his late endresults were somewhat discouraging, he attributes the poor results to the constitutional background of the patients, as some of them were heavy drinkers, two were luetic, one was tuberculous, and one had marked arteriosclerosis.

3. Perforation of ulcer by means of cautery, followed by suture of defect—Balfour. The principle here is that healing will take place in a similar manner to the mechanism of healing following suture of a natural perforation. However, this is fallacious, for during the course of a slowly penetrating and perforating lesion, reparative processes have been going on. Its penetration is accompanied by the formation of protective adhesions, and when perforation does occur, complete recovery often follows simple suture.
